Abstract

Interplate earthquakes occur in areas where an interseismic slip deficit or strain accumulates on the plate interface. Because the slip deficit rate is larger in the mechanical locking zone than that on the plate interface around it, it is essential to reveal the spatial distribution of interplate mechanical locking to accurately evaluate seismic (and accompanying tsunami) potential at subduction zones. Many previous studies estimated slip deficit rate distributions from geodetic observation data based on a pure kinematic framework in which fault dislocation and elastic response at the surface are considered without any mechanical constraints; using this approach, it is impossible to identify the mechanically locked zone from the estimated slip deficit rate distributions. To overcome this limitation, this study developed a new physical model that describes the relation between the mechanical locking on the plate interface and surface crustal deformation by considering the mechanical constraints on the plate interface. The proposed model was incorporated in an inversion approach adopting the replica Monte Carlo method, based on Bayesian estimation, to estimate mechanical locking distributions along the subduction zone based on geodetic observation data. This model was first applied to onshore and seafloor geodetic observation data in northeast Japan during the interseismic period to estimate mechanical locking distributions along the Japan and Kuril Trenches; next, it was applied to onshore and seafloor geodetic observation data in southwest Japan during the interseismic period to estimate mechanical locking distributions along the Nankai Trough. For northeast Japan, two mechanical locking segments were estimated on the plate interface where the 2011 Mw 9.0 Tohoku earthquake occurred. The results obtained by the model indicate that the coseismic slip area is significantly larger than the mechanical locking zone, and strong motion generation areas tended to be located at the edges of mechanical locking distributions. These findings imply that the model can be

used to predict coseismic slip areas, brittle rupture, accompanying slip areas, and potential strong motion generation areas of future earthquakes. For southwest Japan, four mechanically locked segments were estimated along the Nankai Trough. Clear complementation between the mechanical locking distribution and the slow earthquake occurrence zone, implying the capability of estimation of the frictional states on the plate interface, were identified. Furthermore, it was predicted that potential strong motion generation areas along the Nankai Trough may be larger than that along the Japan Trench. Applying the new model to subduction zones as well as splay or inland faults may enable the advanced evaluation of seismic hazard for interplate and intraplate earthquakes globally.

Acknowledgements

Finally, I would like to thank my father, mother, and older brother, who supported me both financially and emotionally throughout my work at Nagoya University. They have always encouraged me to pursue my dream. This thesis would not have been completed without their support. They are the most important people to me, and I dedicate this thesis to them.

Chapter 1
Introduction

The Earth's surface is covered by numerous rigid plates. Due to plate motion and interactions, strain accumulates on plates and plate boundaries. Earthquakes are a common phenomenon by which strain accumulated during interseismic periods is released. In particular, interplate earthquakes occur to release shear strain that has accumulated on plate interfaces during interseismic periods. As interplate earthquakes can cause strong ground shaking and large tsunamis, which lead to serious damages to human life and property, it is essential to assess seismic potential accurately for the mitigation and prevention of earthquake disasters.

Shear strain is accumulated during the interseismic period due to the mechanical locking plate boundary between the upper surface of the subducting plate and the lower surface of the overriding plate. At the mechanically locked zone, the relative motion rate on the plate interface is zero. Following the backslip model (Savage, 1983), in which the kinematic state on the plate interface is expressed as the superimposing of steady slip (plate convergence) and slip in the opposite sense to plate convergence ("backslip" or "slip deficit"), this condition is explained as the slip deficit rate being equal to the plate convergence rate at the mechanically locked zone. In contrast, at the area that is sufficiently far from the mechanical locking zone, the relative motion rate on the plate interface is equal to the plate convergence rate—that is, the slip deficit rate is zero. At the middle regions, the relative motion rate and slip deficit rate are larger than zero and smaller than the plate convergence rate owing to the spatial continuity of the plate interface.

Surface response due to slip deficits on plate interfaces can be perceived as crustal

deformations that occur during the interseismic period, according to the geodetic observations performed using the Global Navigation Satellite System (GNSS). Spatial distributions of the slip deficit rate on the plate interface have been estimated similarly in previous studies (e.g., Carvajal-Soto et al., 2020; Hanifa et al., 2014; Loveless & Meade, 2010; Métois et al., 2016; Villegas‑Lanza et al., 2016; Wallace, 2004). Furthermore, transient coseismic or postseismic slip distributions on the plate interface during earthquakes have been estimated using the seismogram data (e.g., Koper et al., 2012; Yagi & Fukahata, 2011; Yamanaka & Kikuchi, 2003) or surface displacement data observed by GNSS (e.g., Klein et al., 2017; Miyazaki et al., 2004; Simons et al., 2011). By comparing slip distributions between interseismic and coseismic (and/or postseismic) periods, good spatial correlation between large coseismic slips and interseismic high slip deficit rate distributions has been revealed (e.g., Hashimoto et al., 2012; Loveless & Meade, 2015; Moreno et al., 2010).

In Japan, there are many onshore GNSS sites that provide high-accuracy crustal deformation data. The Geospatial Information Authority of Japan (GSI) has operated a continuous onshore geodetic observation network (GEONET) covering the Japan archipelago since the 1990s (Nakagawa et al., 2009). Currently, approximately 1,300 GEONET sites are in operation. Using onshore crustal deformation data, interplate coupling distributions have been estimated along the subduction zone (Hashimoto et al., 2009, 2012; Liu et al., 2010; Loveless & Meade, 2010, 2015; Suwa et al., 2006). However, the resolution power in offshore regions, which comprise the majority of possible megathrust earthquake sources, is typically poor owing to the long distance from onshore GNSS observation sites. Suito (2017a) reported that the GEONET cannot detect events with magnitudes smaller than Mw 6.5 on the Pacific Plate and Mw 6.0 on the Philippine Sea Plate; these data were derived from a simple simulation in which the

displacement at GEONET sites due to fault slip on the plate interface was calculated on the basis of elastic half space. Thus, it is essential to observe seafloor offshore crustal movements to enhance the resolution power and detect interplate coupling distributions. Recently, seafloor geodetic observation networks adopting a GNSS/Acoustic combination technique have been developed along subduction zones (Kido et al., 2015; Tadokoro et al., 2012; Yokota et al., 2018). The total number of GNSS/A sites has reached approximately 60 around Japan. GNSS/A observations are mainly conducted at Nagoya University and Tohoku University and by the Japan Coast Guard. Using seafloor GNSS/A data, it is possible to capture offshore crustal displacement fields in and around Japan.

Most previous studies, including those cited above, have estimated spatial distributions of the interplate slip deficit or the interplate coupling coefficient, which is the ratio between the slip deficit rate and plate convergence rate; these studies were conducted using the pure kinematic model (Figure 1.1(a)) wherein the coupling states (coupling coefficients or slip deficit rates) are estimated independently for each subfault or by using smoothing operations that are not based on actual physics of the area (e.g., Hashimoto et al., 2012; Kimura et al., 2019; Liu et al., 2010; Loveless & Meade, 2010; Nishimura et al., 2018; Suwa et al., 2006). This method is very simple and can be used to estimate interplate coupling distributions that can explain observed crustal deformations without considering any mechanical constraints of the plate interface. However, due to its simplicity, it exhibits the following limitations. First, because the model does not consider physical continuity such as stress or slip continuity based on actual mechanics, estimated coupling distributions may exhibit radical changes at adjacent subfaults, implying the existence of an artificial stress. Second, because the coupling state estimates are expressed with kinematic values, such as slip deficit rate or coupling coefficient, the mechanical locking condition on the plate interface cannot be determined from the estimated coupling

distribution. The plate interface exhibiting high slip deficit rate is not always mechanically locked. Nevertheless, some previous studies assumed the region where the high slip deficit rate or coupling coefficient were estimated as "asperity" and assessed the seismic potential from the coupling or slip deficit rate distributions using the aforementioned model. The maximum coseismic slip magnitude on the "asperity" can be roughly predicted from the evaluation. However, it must be noted that the earthquake would be nucleated depending on the stress condition and frictional strength (i.e., mechanical states) on the plate interface. Thus, it is essential to estimate the spatial distributions of mechanical locking states on the plate interface. The mechanical state is considered to be equivalent to the frictional state, which can control the slip behaviors on the plate interface. Hence, revealing this can facilitate the prediction of coseismic slip areas, maximum coseismic slip magnitude, and slip behaviors (e.g., brittle rupture, accompanying sliding, slow slip, and short period seismic wave radiation) of future earthquakes.

To overcome these limitations, a new physical model was developed in this study that relates mechanical locking on the plate interface to surface crustal deformations (Figure 1.1(b)). The proposed model enables the direct estimation of mechanical locking distributions and the accompanying slip deficit rates from the observed crustal deformation data. In this model, only two mechanical conditions (known as "binary locking" in Herman & Govers, 2020) were allowed on the plate interface, namely "mechanically locked" and "creeping (unlocked)." In the mechanically locked zone, finite shear tractions work, and the slip deficit whose velocity is equal to the relative block motion (plate convergence) rate exists. Shear strain in the area increases over time. The creeping zone encompasses all plate interface areas outside of the mechanical locking zone. Although shear tractions do not work in the creeping zone, slip deficits whose

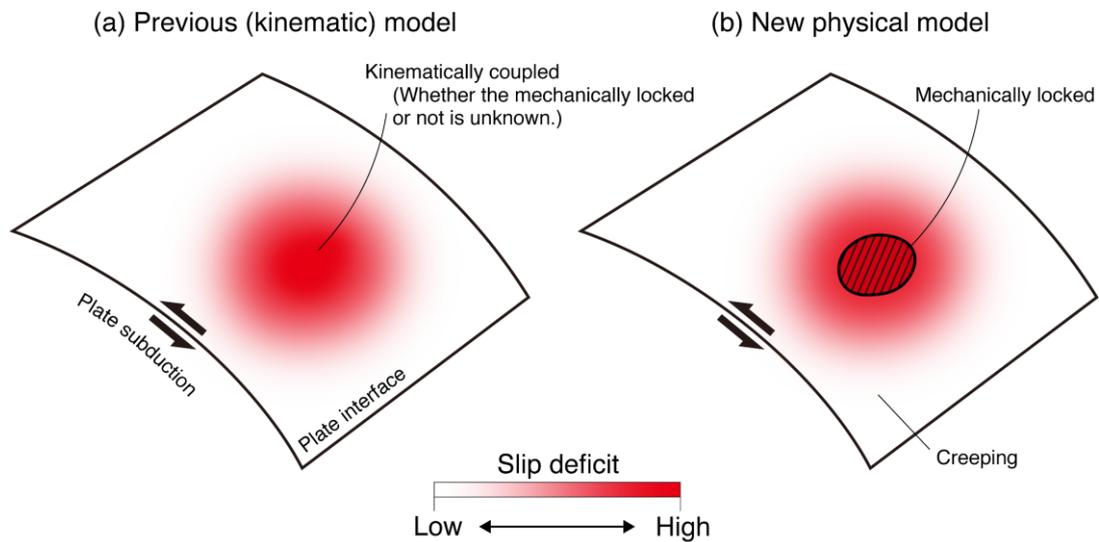

Figure 1.1. Concept of "locking" states on the plate interface in the previous (kinematic) and proposed models. (a) In the pure kinematic model, "locking" states indicate kinematic states, such as slip deficit rate or coupling coefficient. (b) In the new physical model, "locking" states directly represent the mechanical states, that is, mechanically locked (hatched area) or creeping (non-hatched area).

velocity is zero or less than the relative block motion rate are accompanied by mechanical locking to satisfy the constant strain states. The slip deficit rate in the creeping zone decays with the distance from the mechanical locking zone. While the absolute (background) strain value is not clear in the creeping zone, shear strain does not change over time to satisfy the constant strain state in the creeping zone. This concept is based on the suggestion that both the mechanical locking zones and the plate interface around them should accumulate slip deficits owing to the mechanical continuity of the plates (Wang & Dixon, 2004). It is worth noting that other mechanical effects, such as friction, viscosity, and their heterogeneities, are not explicitly modeled in this study. Similar concepts have been modeled in previous studies (e.g., Almeida et al., 2018; Bürgmann, 2005; Herman et al., 2018). And inversion methods to estimate the mechanical locking distributions from the geodetic observation data were proposed (Herman & Govers, 2020;

Johnson & Fukuda, 2010; Ortega, 2013).

Mechanical locking distributions have not been estimated along the subduction zone in Japan, where megathrust earthquakes have repeatedly occurred. Revealing the mechanical locking distributions along the Nankai Trough is an urgent task because the average recurrence interval of the megathrust earthquake in this area is 100–150 years (Ando, 1975; Garrett et al., 2016), and over 70 years have passed since the last megathrust earthquakes of 1944 (M 7.9) and 1946 (M 8.0). Thus, this study aims developed a new physical model based on the concept described above to estimate mechanical locking distributions along subduction zones in Japan using geodetic observation data. The remainder of this thesis is constructed as follows. In Chapter 2, a model is proposed that describes the relation between interplate mechanical locking and surface crustal deformation, including the block motion and block internal strain effects; subsequently, a novel inversion method is presented for estimating mechanical locking distributions using the Bayesian approach based on geodetic observation data. The proposed model was first applied to northeast Japan to estimate mechanical locking distributions along the Kuril and Japan Trenches. In this region, Mw 8.0 Tokachi Earthquake and Mw 9.0 Tohoku Earthquake occurred in 2003 and 2011, respectively. Interplate kinematic coupling distributions were estimated using onshore GNSS data prior to the 2003 Tokachi Earthquake. Coseismic slip distributions and strong motion generation areas of the two earthquakes were also estimated from the seismic waveform data. Thus, the estimated mechanical locking distribution using the new physical model was compared to these distributions. The estimated distributions were also compared to the kinematic coupling distributions that were estimated in previous studies. This section also presents the results of tests in which the configuration of the block divisions and the plate interface geometries were changed to verify the effects caused by these configurations. In Chapter

3, the proposed model was applied to estimate mechanical locking distributions along the Nankai Trough in southwest Japan. I compared the results with the kinematic coupling distributions estimated by Kimura et al. (2019) to reveal the spatial relationship between the mechanical locking and kinematic coupling estimated from geodetic observation data. Moreover, the results from the comparison of the estimated mechanical locking distributions with slow earthquakes detected during the interseismic period and strong motion generation areas of 1944 Tonankai and 1946 Nankai earthquakes are presented to evaluate the frictional states on the plate interface and determine possible factors causing the radiation of the short-period seismic waves from the strong motion generation area, respectively. In Chapter 4, I summarize the main results of this study and describe the implications of the results. I also present suggestions for applying the proposed model and the findings from this study in future research.

Chapter 2
Physical modeling of mechanical locking and its application in northeast Japan

2.1. Introduction

In this chapter, a newly developed physical model is reported that relates mechanical locking on the plate interface to surface crustal deformation. An inversion adopting the Bayesian approach with the proposed model was achieved for onshore and seafloor geodetic observation data in northeast Japan to estimate mechanical locking distributions along the Kuril and Japan Trenches.

In northeast Japan, the Pacific Plate subducts beneath the overriding plates along the Japan and Kuril Trench with a convergence rate of ~9 cm/yr (DeMets et al., 2010). The interplate earthquakes of around M 7 have repeatedly occurred at an interval of approximately 30 years along the Japan Trench (Yamanaka & Kikuchi, 2004). Large (> M 8) interplate earthquakes, such as the Mw 8.2 Tokachi Earthquake in 1968 and the Mw 9.0 Tohoku Earthquake in 2011 have occurred at longer intervals. Along the Kuril Trench, earthquakes with > M 8 have recurred at an average interval of 100 years (Satake, 2015). In addition, the occurrence of unusual tsunami earthquakes at an interval of ~500 years, sometimes called the "17 century type earthquake," was implicated from the geological records at coastal region (Satake et al., 2008). The rupture (coseismic slip) areas, sometimes called "asperities," of earthquakes have previously been estimated using seismic waveform data (Nagai et al., 2001; Yagi, 2004; Yamanaka & Kikuchi, 2004), tsunami data (Ioki & Tanioka, 2016; Tanioka et al., 1996), and geodetic data (Iinuma et al., 2012; Miyazaki & Larson, 2008; Simons et al., 2011). In northeast Japan, interplate coupling distributions prior to the 2003 Tokachi Earthquake (or 2011 Tohoku Earthquake)

have been estimated using onshore GNSS observation data based on the pure kinematic model (Hashimoto et al., 2009; Loveless & Meade, 2010; Suwa et al., 2006). Moreover, interplate coupling conditions have been discussed on the basis of seafloor GNSS/A observation data in the Tohoku region (Sato et al., 2013). The comparison of interplate coupling distributions in the interseismic period and coseismic slip distributions have been studied previously (Hashimoto et al., 2012; Itoh et al., 2019; Loveless & Meade, 2015). However, mechanical locking distributions have not been estimated in this region. Thus, the relationship among the mechanical locking, kinematic coupling, and coseismic (postseismic) slip distributions is not clear.

As northeast Japan is a rare region where dense geodetic observation data (including seafloor GNSS/A data as well as onshore GNSS data) prior to the megathrust earthquake are available, it is possible to verify the proposed model by comparing interseismic mechanical locking, kinematic coupling, and coseismic slip distributions. The proposed model was first applied to the northeast Japan region. Because the onshore GNSS (GEONET) observation data prior to the 2003 Tokachi Earthquake and seafloor GNSS/A observation data as well as onshore GNSS data prior to the 2011 Tohoku Earthquake are available, it is possible to estimate the mechanical locking distribution at the interseismic period and compare it with coseismic (postseismic) slip distributions, hypocenters, and strong motion generation areas. The performance of the proposed model was verified by this comparison.

2.2. Methods and data

In this chapter, I first describe the proposed model that relates the mechanical locking on the plate interface to surface crustal deformations. This model was applied to geodetic observation data in northeast Japan to estimate mechanical locking distributions along the

Kuril and Japan Trenches (reported in this chapter) and in southwest Japan to estimate mechanical locking distributions along the Nankai Trough (reported in Chapter 3). This study adopted a replica exchange Monte Carlo (REMC) method, which utilizes Bayesian estimation, to estimate mechanical locking distributions from the surface displacement rate dataset. I present the algorithm of the REMC method and the configuration of a priori distributions. Then, I briefly denote the data processing procedure for obtaining the surface displacement rate that was used for the Bayesian inversion. Finally, I described the block division configurations and plate interface geometry used in the analysis.

2.2.1. Physical model relating mechanical locking to crustal deformations

The surface displacement v_{cal} is expressed as a sum of the rigid block motion (rotation) v_{rigid}, surface response of the slip deficit on the plate interface $v_{\mathrm{sd\_plate}}$, surface response of the slip deficit on the inland block boundary $v_{\mathrm{sd\_inland}}$, and internal strains v_{instrain}.

$$v_{\mathrm{cal}} = v_{\mathrm{rigid}} + v_{\mathrm{sd\_plate}} + v_{\mathrm{sd\_inland}} + v_{\mathrm{instrain}} \qquad (1)$$

This formulation is sometimes called the block motion (block fault) model (e.g., Carvajal-Soto et al., 2020; Kimura, Ito, et al., 2019; Loveless & Meade, 2010; Nishimura et al., 2018). The term v_{rigid} can be described by using Euler vectors $\boldsymbol{\omega}$ as follows:

$$v_{\mathrm{rigid}} = \boldsymbol{\omega}_{\mathrm{i}} \times \boldsymbol{r}_{\mathrm{k}}, \qquad (2)$$

where $\boldsymbol{r}$ is the location vector, and subscripts i and k denote the block and site,

respectively. Surface displacement can be expressed by rigid motion v_{rigid} because the plate tectonics theorem assumes the medium of the plate or block as the rigid body. However, actual plates or blocks deform elastically due to tectonics such as plate subduction or interactions owing to plate motion. Therefore, the proposed model considers these deformations from second to fourth terms in the right-hand side in Equation (1). The second term $v_{\text{sd\_plate}}$ is the core of this model because it includes the elastic response from the mechanical locking on the plate interface. This model allows for two locking states on the plate interface: mechanically locked (in which finite shear traction is working on the plate interface) and creeping (in which the zero-shear traction is working on the plate interface). The term $v_{\text{sd\_plate}}$ can be expressed as follows:

$$v_{\text{sd\_plate}} = G_{\text{l}}\dot{s}_{\text{l}} + G_{\text{c}}\dot{s}_c, \qquad (3)$$

where $\dot{s}_{\text{l}}$ and $\dot{s}_c$ are the slip deficit rate on the mechanical locking subfaults and on the creeping subfaults, respectively, and G_{l} and G_{c} are the Green's functions describing the relationship between the slip deficit rates on the mechanically locked subfaults and creeping subfaults to surface displacement rates, respectively. In this study, the elastic half space medium was assumed, and the aforementioned Green's functions were calculated on the basis of triangular dislocation model (Meade, 2007). The terms $\dot{s}_{\text{l}}$ and $\dot{s}_{\text{c}}$ are related to the mechanical constraints, namely, constant strain states in the creeping region. Shear strains due to $\dot{s}_{\text{l}}$ and $\dot{s}_{\text{c}}$ are calculated as follows. First, shear strains on the creeping zone $\dot{\varepsilon}_{\text{l}}$ due to the slip deficit rates on imposed in the mechanical locking zone $\dot{s}_{\text{l}}$ are determined using the following equation:

$$\dot{\varepsilon}_{\text{l}} = G_{I}^{\varepsilon}\dot{s}_{\text{l}}, \qquad (4)$$

where $\boldsymbol{G}_{\mathrm{l}}^{\varepsilon}$ is a coefficient matrix that relates $\dot{\boldsymbol{s}}_{\mathrm{l}}$ to $\dot{\boldsymbol{\varepsilon}}_{\mathrm{l}}$. Next, similarly, shear strains on the creeping zone $\dot{\boldsymbol{\varepsilon}}_{\mathrm{c}}$ due to the slip deficit rates induced in the creeping zone $\dot{\boldsymbol{s}}_{\mathrm{c}}$ are calculated as follows:

$$\dot{\boldsymbol{\varepsilon}}_{\mathrm{c}} = \boldsymbol{G}_{\mathrm{c}}^{\varepsilon}\dot{\boldsymbol{s}}_{\mathrm{c}}, \tag{5}$$

where $\boldsymbol{G}_{\mathrm{c}}^{\varepsilon}$ is a coefficient matrix that relates $\dot{\boldsymbol{s}}_{\mathrm{c}}$ to $\dot{\boldsymbol{\varepsilon}}_{\mathrm{c}}$. The coefficient matrices $\boldsymbol{G}_{\mathrm{l}}^{\varepsilon}$ and $\boldsymbol{G}_{\mathrm{c}}^{\varepsilon}$ in this study were calculated on the basis of triangular dislocation model (Meade, 2007), as same as $\boldsymbol{G}_{\mathrm{l}}$ and $\boldsymbol{G}_{\mathrm{c}}$. The total strain rate on the creeping subfaults is the sum of $\dot{\boldsymbol{\varepsilon}}_{\mathrm{l}}$ and $\dot{\boldsymbol{\varepsilon}}_{\mathrm{c}}$. This model assumes the constant strain state on the creeping zone, that is, the shear strain does not temporarily change on the creeping zone. To satisfy this constrain, the sum of $\dot{\boldsymbol{\varepsilon}}_{\mathrm{l}}$ and $\dot{\boldsymbol{\varepsilon}}_{\mathrm{c}}$ becomes zero as follows:

$$\dot{\boldsymbol{\varepsilon}}_{\mathrm{l}} + \dot{\boldsymbol{\varepsilon}}_{\mathrm{c}} = \boldsymbol{0}. \tag{6}$$

This equation implies that shear strain on the creeping subfaults due to slip deficits on mechanically locked subfaults is released by shear strains owing to the induced slip deficit on creeping subfaults. Substituting Equation (4) and (5) into Equation (6), the relationship between imposed slip deficit on mechanically locked subfaults and induced slip deficit on the creeping subfaults can be derived as follows:

$$\dot{\boldsymbol{s}}_{\mathrm{c}} = -(\boldsymbol{G}_{\mathrm{c}}^{\varepsilon})^{-1}\boldsymbol{G}_{\mathrm{l}}^{\varepsilon}\dot{\boldsymbol{s}}_{\mathrm{l}}. \tag{7}$$

The slip deficit rate on mechanically locked subfaults is equivalent to the relative block

motion rate that is the difference between the two rigid block motion rates. Thus,

$$\dot{s}_l = (\boldsymbol{\omega}_e - \boldsymbol{\omega}_f) \times \boldsymbol{r}_l, \tag{8}$$

where $\boldsymbol{r}_l$ denote the location vector of mechanically locked subfaults, and $\boldsymbol{\omega}_e$ and $\boldsymbol{\omega}_f$ denote the Euler vectors of the block e and f, respectively. Note that actual relative block motion, which is described in Equation (8), should be calculated at the surface and not at the subfault location because the relative block motion rate at a block boundary should be the same between the surface and subsurface. However, the difference between the distance from Earth's center to the subfault center and that to the surface where the subfault center is projected is within 80 km at maximum. This minute difference in distance accounts for only ~1% of the difference between actual relative block motion and that calculated using Equation (8), which is almost same as the uncertainties of the crustal deformation data. Thus, it is reasonable to approximate the relative block motion rate using Equation (8). Considering Equation (8), Equation (7) can be modified as follows:

$$\dot{s}_c = -(\boldsymbol{G}_c^\varepsilon)^{-1} \boldsymbol{G}_l^\varepsilon (\boldsymbol{\omega}_e - \boldsymbol{\omega}_f) \times \boldsymbol{r}_l \tag{9}$$

Using Equation (8) and (9), Equation (3) can be revised as follows:

$$\boldsymbol{v}_{sd\_plate} = [\boldsymbol{G}_l - \boldsymbol{G}_c(\boldsymbol{G}_c^\varepsilon)^{-1} \boldsymbol{G}_l^\varepsilon](\boldsymbol{\omega}_e - \boldsymbol{\omega}_f) \times \boldsymbol{r}_l \tag{10}$$

Using Equation (10), total slip deficits on the plate interface and the surface response from the slip deficits can be calculated if the mechanically locked location is
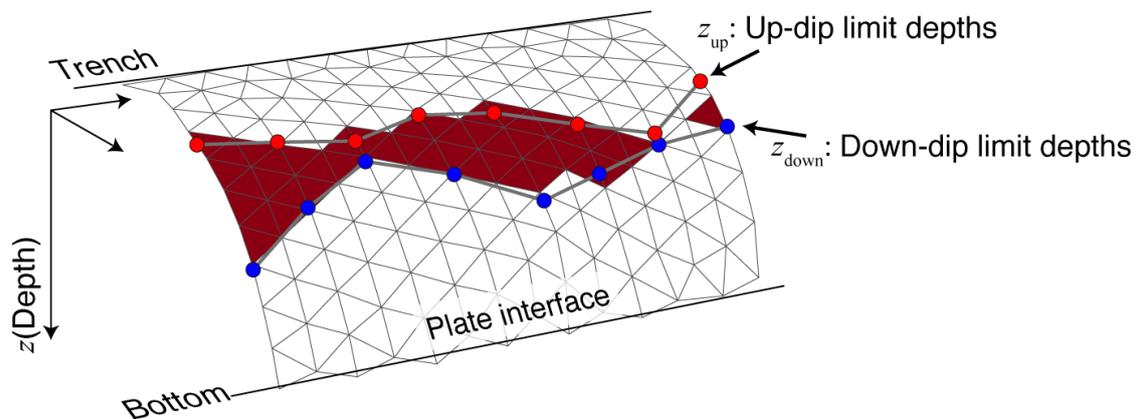

Figure 2.1. Schematic imaging of the mechanical locking zone on the plate interface. Each triangle indicate subfaults. Red subfaults are mechanically locked. The remaining white subfaults are creeping. Subfaults were determined to be mechanically locked based on the centroid depths of subfaults and up-dip (red circles) and down-dip (blue circles) limit depths, as follows: If the centroid of the subfault is between the up- and down-dip limit depths, the subfault is considered mechanically locked, else, the subfault considered creeping.

known. However, which subfaults are mechanically locked is unknown. Hence, parameterization of the mechanically locked zone is necessary to invert the surface crustal deformation and determine the mechanical locking distributions. This model assumes that the belt-like mechanical locking zone is prescribed by the up- and down-dip depth limitation (z_{up} and z_{down}, respectively), as shown as Figure 2.1. The subfaults whose center is located between z_{up} and z_{down} are assumed to be mechanically locked. The combination of z_{up} and z_{down} are the model parameters to be estimated. Previous studies parameterized the locking states for each subfault using binary values, 0 (creeping) and 1 (mechanical locking), and estimated the locking states for each subfault independently (Herman & Govers, 2020; Johnson & Fukuda, 2010). Nevertheless, it is considered that the parameterization to identify mechanically locked subfaults proposed in this study is better because following problems appear in the previous method: the

computational time become significantly longer as the number of subfault increases; complex mechanical locking distributions would be estimated if the subfault size is small. As the subducting plate interface is the focus of this study, the surface response from the slip deficits on the inland block boundaries was calculated on the basis of the kinematic framework, following previous studies (Carvajal-Soto et al., 2020; Kimura et al., 2019; Loveless & Meade, 2010; Nishimura et al., 2018). In the kinematic framework, the orientation and degree of the slip deficit rate is defined as the reverse orientation of the relative block motion and the rate produced by the relative block motion rate and coupling coefficient, respectively. Then, the slip deficit rate on the subfaults of the inland block boundaries $\dot{\boldsymbol{s}}_\mathrm{b}$ can be expressed as follows:

$$\dot{\boldsymbol{s}}_\mathrm{b} = C_\mathrm{b}(\boldsymbol{\omega}_{\mathrm{e}\prime} - \boldsymbol{\omega}_{\mathrm{f}\prime}) \times \mathbf{r}_\mathrm{b}, \tag{11}$$

where the $\boldsymbol{\omega}_{\mathrm{e}\prime}$ and $\boldsymbol{\omega}_{\mathrm{f}\prime}$ denote the Euler vectors of two adjacent blocks, $\mathbf{r}_\mathrm{b}$ denotes the location vector of the subfaults on the inland block boundaries, C_b denotes the coupling coefficient of the subfault on the inland block boundaries. Then, $\boldsymbol{v}_{\mathrm{sd\_inland}}$ is calculated as follows:

$$\boldsymbol{v}_{\mathrm{sd\_inland}} = \boldsymbol{G}_\mathrm{b}C_\mathrm{b}(\boldsymbol{\omega}_{\mathrm{e}\prime} - \boldsymbol{\omega}_{\mathrm{f}\prime}) \times \mathbf{r}_\mathrm{b}, \tag{12}$$

where C_b is the coupling coefficient of the subfault on the inland block boundaries, and $\boldsymbol{G}_\mathrm{b}$ is the Green's function that relates the slip deficit rates of the subfaults on the inland block boundaries to the surface displacement rates. The Green's function $\boldsymbol{G}_\mathrm{b}$ was calculated using the code reported by Meade (2007) as $\boldsymbol{G}_\mathrm{l}$ and $\boldsymbol{G}_\mathrm{c}$. Here, only the positive slip deficit is allowed, and forward slip expressed as the negative slip deficit is not

allowed. Hence, C_b can take any value between 0 and 1. To calculate v_{instrain}, the uniform internal strain was assumed for all blocks. That is,

$$v_{\text{instrain}} = \dot{E}r'_{\text{k}}, \tag{13}$$

where $\dot{E}$ and r'_{k} denote the internal strain rate tensor and the site location whose origin is the center of the site network inside each block, respectively. Using Equations (2), (10), (12), and (13), Equation (1) can be expressed as follows:

$$
\begin{aligned}
v_{\text{cal}} = {} & \omega_{\text{i}} \times r_{\text{k}} \\
& + [G_{\text{l}} - G_{\text{c}}(G_{\text{c}}^{\varepsilon})^{-1}G_{\text{l}}^{\varepsilon}](\omega_{\text{e}} - \omega_{\text{f}}) \\
& + G_{\text{b}}C_{\text{b}}(\omega_{\text{e}'} - \omega_{\text{f}'}) \times r_{\text{b}} \\
& + \dot{E}r'_{\text{k}}
\end{aligned}
\tag{14}
$$

Equation (14) can be rewritten as the observation equation form as follows:

$$d = g(m), \tag{15}$$

where d is the observation vector, m is the model parameter vectors, and $g(\ )$ is the nonlinear operator that relates m to d. Because the model parameters m, which contains the Euler vector ω, up- and down-dip limitation depths of the mechanical locking zone (z_{up} and z_{down}, respectively), coupling coefficient C_b, and the internal strain rate $\dot{E}$ cannot be estimated uniquely, I adopted the Bayesian approach to obtain a probability density function (PDF) of m, which is described in the next section.

2.2.2. Bayesian estimation

I estimated all model parameters simultaneously from an inversion. The observation equation is described as Equation (15). Because the model parameters cannot be solved uniquely, a Bayesian estimation was used to estimate the PDFs of all model parameters. The Bayesian estimation used in this study was based on Bayes' theorem, and the formulation is expressed as

$$p(\boldsymbol{m}|\boldsymbol{d}) = \frac{p(\boldsymbol{d}|\boldsymbol{m})p(\boldsymbol{m})}{p(\boldsymbol{d})}, \tag{16}$$

where $p(\boldsymbol{m})$ is a prior PDF of model parameters, $p(\boldsymbol{d})$ is the PDF of the observations (marginal PDF), $p(\boldsymbol{d}|\boldsymbol{m})$ is a conditional PDF of $\boldsymbol{d}$ given $\boldsymbol{m}$ and referred as the likelihood function, and $p(\boldsymbol{m}|\boldsymbol{d})$ is a conditional PDF of $\boldsymbol{m}$ given $\boldsymbol{d}$ that is referred as the posterior PDF. Because the observations are now fixed, $p(\boldsymbol{d})$ becomes a constant. Then, Equation (16) can be rewritten as follows:

$$p(\boldsymbol{m}|\boldsymbol{d}) \propto p(\boldsymbol{d}|\boldsymbol{m})p(\boldsymbol{m}). \tag{17}$$

I define the likelihood function $p(\boldsymbol{d}|\boldsymbol{m})$ using the L_1 norm as follows:

$$p(\boldsymbol{d}|\boldsymbol{m}) = \exp\left(-\sum_{i=1}^{M}\left|\frac{d_i - g(m)}{\sigma_i}\right|\right), \tag{18}$$

$$\sigma_i = \sqrt{\sigma_{obs_i}^2 + \sigma_{model_i}^2}, \tag{19}$$

where M denotes the number of observation data, that is, three times number of sites, and σ_i is the uncertainty of d_i. The L_1 norm is useful for measuring the goodness of model parameter realization with lower sensitivity for outliers (Menke, 2012). The uncertainties accompanying the data contains the observation error σ_{obs} and the model error σ_{model}. While the observation error can be identified from the data processing, any a priori information for the model error is not given. Thus, this value was assumed as 1 mm/yr in this study.

Prior PDFs of the model parameters are defined as follows. For z_{up} and z_{down}, the following three states were allowed: z_{up} and z_{down} can cross; z_{up} can range between the trench depth minus $2\times z_W$ and bottom depths, where z_W is the trench and bottom depths difference; z_{down} can range between the trench depth and bottom depth plus $2\times z_W$. These constraints are similar to those reported by Ortega (2013), but he did not allow the crossing of z_{up} and z_{down}. Formulating these constraints, prior PDFs z_{up} and z_{down} becomes

$$p\left(z_{up}\right) = \begin{cases} 1, & \left(z_{trench} - 2z_W \leq z_{up} \leq z_{bottom}\right) \\ 0, & (otherwise) \end{cases}, \qquad (20)$$

and

$$p(z_{down}) = \begin{cases} 1, & \left(z_{trench} \leq z_{down} \leq z_{bottom} + 2z_W\right) \\ 0, & (otherwise) \end{cases}, \qquad (21)$$

where z_{trench} and z_{bottom} indicate the model region trench and bottom depths, respectively. In the model region of northeast Japan, z_{trench} and z_{bottom} were adopted to be 0 km and 80 km in depth, respectively. Then, z_W becomes 80 km. Although one may assume that z_{up} and z_{down} should be sampled within the model region depths,

sampling outside the model region depths is permitted because the mixing rate becomes considerably lower, and the calculation cost increases significantly with a strict constraint that does not allow sampling outside of the model region depths. The coupling coefficient C_{b} is allowed to range from 0–1, and a prior PDF of it can be formulated as follows:

$$p(C_{\mathrm{b}}) = \begin{cases} 1, & (0 \le C_{\mathrm{b}} \le 1) \\ 0, & (otherwise) \end{cases}.$$

(22)

For the Euler vector and internal strain rate, constraints were not operated. Thus, uniform distributions are adopted according to prior PDFs:

$$p(\boldsymbol{\omega}) = 1,$$

(23)

and

$$p(\dot{E}) = 1.$$

(24)

The Bayesian inversion in this study cannot be solved analytically. Thus, I adopted the REMC method (Earl & Deem, 2005; Habeck et al., 2005; Swendsen & Wang, 1986), which is a Markov chain Monte Carlo (MCMC) method (Hastings, 1970; Metropolis et al., 1953) to obtain the posterior PDFs of all model parameters simultaneously. A Monte Carlo algorithm conducts repeated random sampling to obtain numerical results, and a Markov chain is a stochastic model in which the current state only depends on the previous state (Hastings, 1970; Metropolis et al., 1953). The MCMC method enables us to obtain the PDFs of all model parameters numerically even if the posterior PDF cannot be solved analytically. The standard MCMC method is useful particularly in the case that the posterior PDF of the model parameters has a unimodal distribution. However,

posterior PDFs commonly have multimodal distributions in practice. In this case, standard MCMC sampling is sometimes trapped in local lobes. Adopting the REMC method would overcome the trapping problem and is capable of sampling more effectively than the standard MCMC method. REMC conducts the tempering of the sampling chains at different densities during the sampling processes. Tempering relaxes the likelihood function that effectively flattens peaks, thereby facilitating Markov chain transitions. By simulating numerous parallel sampling and exchanging the chains, sampling efficiency is improved, and the multimodal PDF can be estimated far more easily when compared to the results obtained using general MCMC methods.

A primary element of REMC sampling is the standard MCMC algorithm. Here, I first summarize a major algorithm of the standard MCMC method, called the Metropolis–Hasting (M–H) algorithm (Hastings, 1970; Metropolis et al., 1953).

The M–H method consists of the following five steps:

Step 1: Set the initial value of all model parameters m_0 and calculate the likelihood $p(\boldsymbol{d}|\boldsymbol{m}_0)$.

Repeat Step 2 to Step 5 until the posterior PDF converges.

Step 2: Propose a candidate model parameter $\boldsymbol{m}^*$ from the proposal PDF with respect to the current (e.g., when the iteration number equals n) sample $\boldsymbol{m}_\text{n}$. Here, although the form of the proposal PDF can control the convergence rate, it is known that posterior PDF does not depend on the proposal PDF. In this study, I select the normal distribution function, that is, $N(\boldsymbol{m}_\text{n}, \boldsymbol{\gamma})$, as the proposal PDF. The standard deviation $\boldsymbol{\gamma}$ plays a roll of scale factor of the distance between $\boldsymbol{m}_\text{n}$ and $\boldsymbol{m}^*$.

Step 3: Calculate the "acceptance probability" r using the posterior PDF with respect to the candidate $\boldsymbol{m}^*$ and the posterior PDF with respect to the current model $\boldsymbol{m}_\text{n}$, as follows:

$$r = min\left(1, \frac{p(\boldsymbol{d}|\boldsymbol{m}^*)p(\boldsymbol{m}^*)}{p(\boldsymbol{d}|\boldsymbol{m}_n)p(\boldsymbol{m}_n)}\right), \tag{25}$$

where the function $min(A, B)$ responds the minimum value from A or B.

Step 4: Determine whether the candidate $\boldsymbol{m}^*$ is accepted or rejected on the basis of acceptance ratio defined as Equation (25) . If $\boldsymbol{m}^*$ is accepted, the current $\boldsymbol{m}_n$ moves to the candidate as $\boldsymbol{m}_{n+1} = \boldsymbol{m}^*$; otherwise, the current $\boldsymbol{m}_n$ remains as $\boldsymbol{m}_{n+1} = \boldsymbol{m}_n$.

Step 5: Draw the posterior PDF $p(\boldsymbol{m}_n|\boldsymbol{d})$ from the sampling $\boldsymbol{m}_n$.

Next, I summarized the REMC algorithm. Let us consider the sampling chains as follows:

$$p(m_i|d, T_i) \propto p(m_i|d)^{1/T_i}, \tag{26}$$

where the subscript i indicates the "chain number," and T_i (i $= 1,2, …, N$) represents the temperature of each chain. The total number of chains is N. T_i satisfies the rule $1 = T_1 < T_2 < T_2 < … < T_N$. As the chain number increases (i.e., as T_i increases), the target PDF becomes smoother. The REMC algorithm then proceeds according to the following steps:

Step 1: Set the initial value of all model parameters $m_i^{(0)}$ and calculate the likelihood $p\left(d\middle|m_i^{(0)}, T_i\right)$ for each chain.

Repeat Step 2 to Step 4 until the posterior PDF converges.

Step 2: Obtain the next sample $m_i^{(n)}$ following Step 2 to Step 5 of the M–H algorithm.

Step 3: After every several steps, two chains of i-th and (i+1)-th ($1 \le i \le N$) are randomly selected to calculate the "exchanging probability" q as follows:

$$q = min\left(1, \frac{p\left(m_{i+1}^{(n)}\middle|d, T_i\right)p\left(m_i^{(n)}\middle|d, T_{i+1}\right)}{p\left(m_i^{(n)}\middle|d, T_i\right)p\left(m_{i+1}^{(n)}\middle|d, T_{i+1}\right)}\right). \tag{27}$$

Step 4: Exchange current samples between the two chains, that is, $\boldsymbol{m}_{i+1}^{(n)} \leftarrow \boldsymbol{m}_i^{(n)}$ and $\boldsymbol{m}_i^{(n)} \leftarrow \boldsymbol{m}_{i+1}^{(n)}$, with the exchanging probability defined as Equation (27).

Step 5: Draw the posterior PDF $p\left(m_i^{(n)}\middle|d\right)$ from the sampling m_i. The target PDF is $p(m_1|d)$.

For this calculation, the initial conditions of model parameters were set as follows: The initial $\boldsymbol{\omega}$ is estimated considering only the rigid block motion part of the block motion model; the initial z_{up} and z_{down} is a uniquely distributed random value ranging from 0 to 60 km that is consistent with the model region depth ranging; the initial C_b of each subfault is a uniquely distributed random value ranging from 0 to 1; and the initial $\dot{\boldsymbol{E}}$ is a uniquely distributed random value ranging from -10^{-10} to 10^{-10}/yr. The number of iterations and number of chains are 2.08×10^6 and 10, respectively. The temperature of REMC is configured to be a geometric sequence of $T_i = 1.67^{i-1}$ so that $T_{10} = 100$. In this study, 10% of the first iteration sampling was rejected as burn-in. This calculation was performed using MATLAB with a workstation consisting of 44 cores of CPU E5-2699 v4 (2.20 GHz), 5120 CUDA cores of GPU (1455 MHz), and 264 gigabytes memory.

Although all model parameters can be estimated as posterior PDFs simultaneously using the REMC method, I evaluated estimated mechanical locking distributions, which are discussed in the following chapters. The results of rigid motion and internal block

strain rates are summarized in Appendix A.

2.2.3. Crustal deformation data in northeast Japan

The surface displacement rates were used as data for REMC inversion to estimate interplate mechanical locking distributions. In Japan, the onshore GNSS observation network (GEONET) was developed by GSI in 1996, which now operates over 1300 stations. The F3 solutions, which are daily coordinate data from GEONET stations, are available via the GSI homepage (https://terras.gsi.go.jp/). Additionally, seafloor geodetic observation sites employing the GNSS/Acoustic combination technique have been installed along the subduction zone of the Pacific Ocean side from off Nemuro through off Okinawa since the 2000s. I use both onshore and seafloor crustal deformation data in northeast Japan. The data I used in the analysis of northeast Japan and the data processing methods for obtaining displacement rates at each site are outlined below.

The displacement rate and uncertainties of GEONET sites in northeast Japan were estimated using F3 daily coordinate data. The data period is from January 1996 to July 2003. In total, data from 447 GEONET sites were considered. First, I removed the offset included in the coordinate data due to maintenance working such as antenna replacements, based on the offset-correction list provided by GSI (https://mekira.gsi.go.jp/JAPANESE/corrf3o.dat). Then, model displacement was assumed to fit the coordinate data:

$$
\begin{aligned}
x_i^n(t) = a_i^n t + b_i^n \\
+ c_i^n \cos\left(\frac{2\pi t}{365.25}\right) + d_i^n \sin\left(\frac{2\pi t}{365.25}\right) \\
+ e_i^n \cos\left(\frac{4\pi t}{365.25}\right) + f_i^n \sin\left(\frac{4\pi t}{365.25}\right),
\end{aligned}
\tag{28}
$$

where x is the position of a site at time t, a is the mean value of the displacement rate per one year, b is the offset, c and d are amplitudes of annual changes, and e and f are amplitude of semiannual changes. The subscript i indicates a component (east, north, or vertical), and the superscript n indicates a site. The first term on the right-hand side is the trend of displacement, the third and fourth terms are annual changes, and the fifth and last terms are semiannual changes. All parameters described above were estimated simultaneously by the linear least squares, and the a_i^n was used as the average displacement rate per year in this study. Mean uncertainties of displacement rates in the east, north, and vertical components of GEONET sites are 0.1, 0.1, and 0.2 mm/yr, respectively. In general, displacement caused by coseismic and/or postseismic slip has been recorded at some GNSS sites, However, because no major earthquakes have occurred in the study period, I did not model coseismic and/or postseismic displacement in the above equation. Although a seismic swarm occurred offshore at the southeast Izu Peninsula following the Miyake island volcanic eruption and affected the surface velocity near the Izu Peninsula (Kaidzu et al., 2000), no corrections were made because this study focused on surface displacement in Tohoku and Hokkaido, which are north of the Izu region.

Additionally, I estimated the displacement rate and its uncertainties of seafloor GNSS/A sites. The coordinate data were downloaded from the data repository (https://www1.kaiho.mlit.go.jp/KOHO/dataservice/DATA/sgo/, Yokota et al., 2018). The data period is from January 2002 to February 2011. I estimated the displacement rate from the coordinate data by linear regression based on the model equation containing the first and second terms of the right-hand side of the Equation (28). Because the typical observational interval of the GNSS/A site is once or twice in a year, temporal resolution is insufficient to consider annual and/or semiannual displacements. Thus, I did not

consider annual and semiannual displacements in the linear regression for the GNSS/A data. Note that during the GNSS/A data period, two relatively large interplate earthquakes of $>M$ 7 occurred near the seafloor GNSS/A sites off Tohoku, namely: the 2005 *Mw* 7.1 Miyagi Earthquake and 2008 *Mw* 6.9 Fukushima Earthquake (Figure 2.2). Thus, data periods for each seafloor site were selected to avoid the effects of these earthquakes, following the method proposed by Sato et al. (2013) in which the interplate coupling offshore Tohoku prior to the 2011 Tohoku Earthquake was estimated using seafloor GNSS/A observation data. Mean uncertainties of displacement rates in the east and north components of the GNSS/A sites are 16 mm/yr and 14 mm/yr, respectively. Note that the vertical component of the GNSS/A could not be obtained due to lack of coordinate data.

The displacement rates at the GEONET and GNSS/A sites were translated from the International Reference Frame (ITRF) 2005 to Eurasian plate reference frame using the Euler vectors of the Mid-Ocean Ridge VELocity (MORVEL) plate model (DeMets et al., 2010; Figure 2.2; Table C.1).
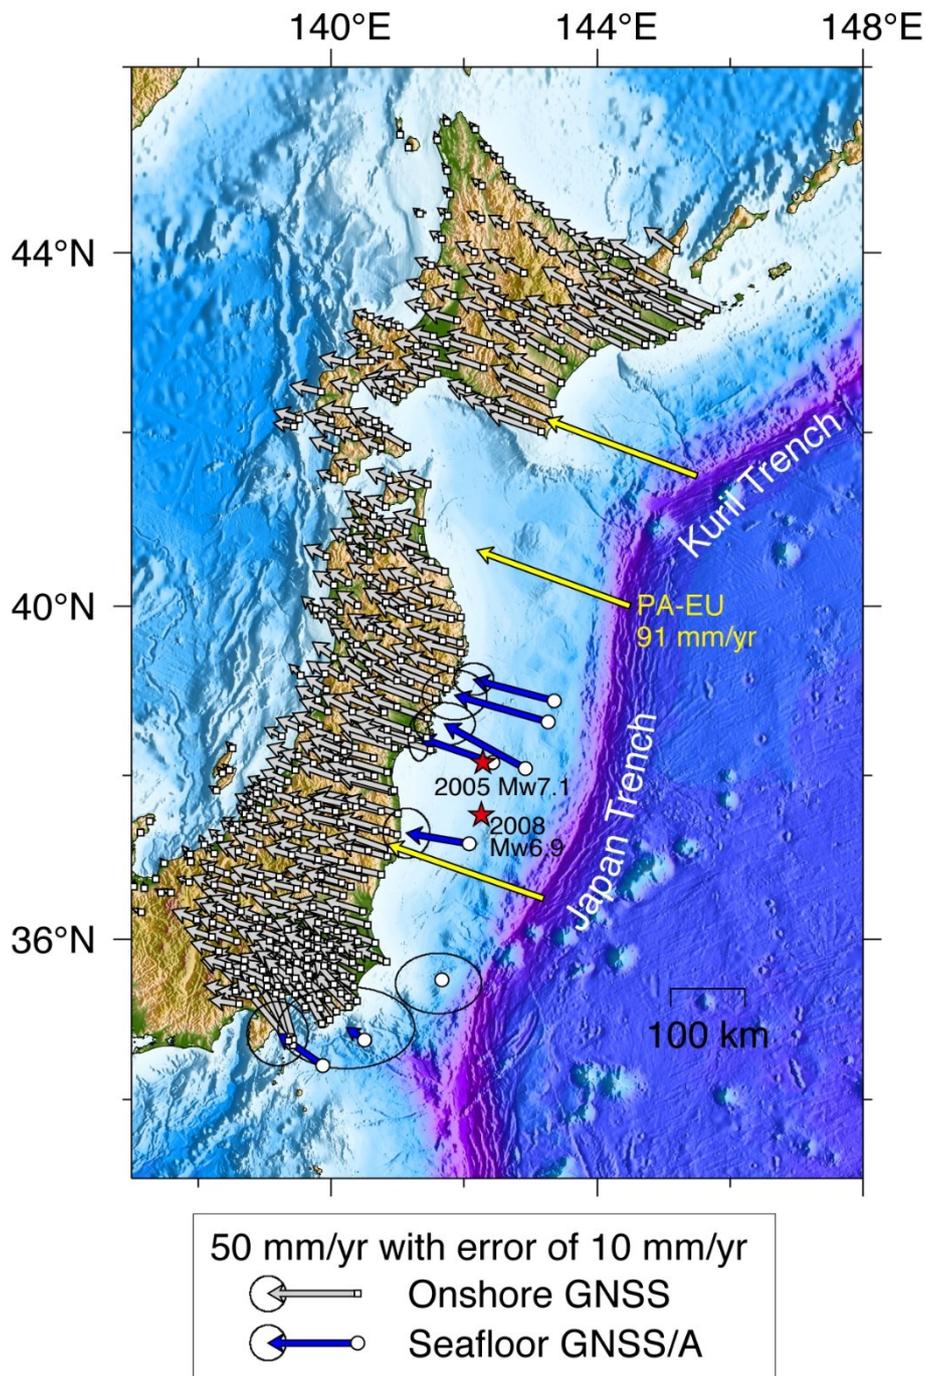

Figure 2.2. Map showing observational data used in this chapter. Gray vectors with white squares and blue vectors with white circles indicate displacement rate vectors at the onshore GNSS (GEONET) and seafloor GNSS/A sites, respectively. Yellow vectors show the Pacific Plate motion relative to the Eurasian plate calculated on the basis of the MORVEL plate motion model (DeMets et al., 2010). Red stars indicate the epicenters of the *Mw* 7.1 Miyagi and *Mw* 6.9 Fukushima earthquakes. Color scale of the map represents the elevation and bathymetry of SRTM30_PLUS (Becker et al., 2009).

2.2.4. Configuration of block boundary and plate interface geometry

According to the global plate model (Bird, 2003), northeast Japan is composed of four major plates: Pacific, Philippine Sea, Amurian, and Okhotsk (North America) Plates. The Pacific Plate subducts beneath the Okhotsk and Philippine Sea Plate along the Kuril, Japan, and Izu–Ogasawara Trenches. The theoretical plate motion rate of the Pacific Plate is approximately 9 cm/yr relative to the Eurasian Plate along the Japan Trench (DeMets et al., 2010). The Philippine Sea Plate subducts beneath the Okhotsk Plate along the Sagami Trough. These plates can be assumed rigid bodies, and their motion is the independent rotation prescribed by Euler vectors. In the regional-scale, the overriding plates can be divided into independent blocks based on geological, geodetic, and seismological features. In the eastern part of Okhotsk Plate, GNSS observation analysis has suggested that there is a long and wide shear concentrating zone extending with NE–SW orientation, called the Niigata–Kobe Tectonic Zone (NKTZ; Sagiya et al., 2000). In the central part of northeast Japan, the long and high Ou Backbone Range extends with approximate N–S orientation. This mountain range is a volcanic front where many active volcanoes are aligned, and many reverse faults exist along the mountain range, with relatively large intraplate earthquakes sometimes occurring along the fault zone (Nakata & Imaizumi, 2002). Furthermore, the strain concentrations along the mountain range are also suggested by the GNSS observations (Miura et al., 2002). This volcanic front extends to Hokkaido, and its direction shifts to NNE–SSW along the Kuril Trench. The forearc side of the volcanic front, called the Outer Kuril Arc, is considered to move westward relative to central Hokkaido (Kimura, 1986). This tectonic motion is often referred to as the Kuril forearc sliver. In northeastern Hokkaido, there are active faults with dominant N–S strikes. Recently, slow slip events have been detected along the fault zone by GNSS
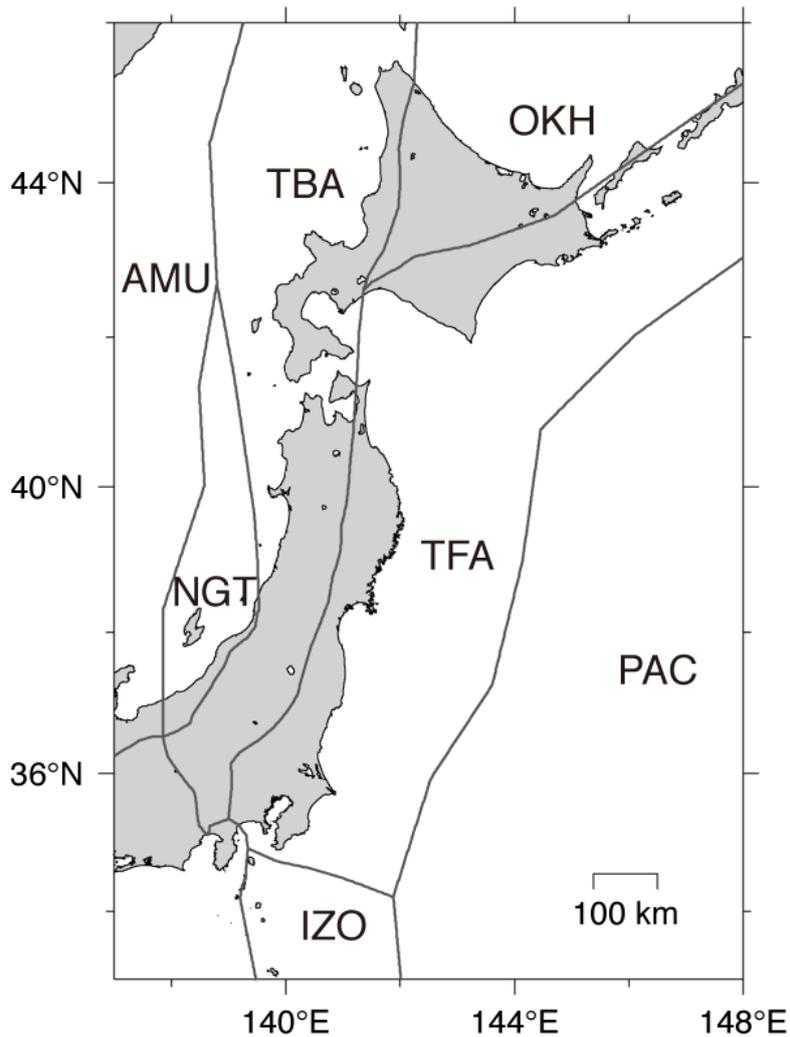

Figure 2.3. Map showing the block boundaries around northeast Japan. Abbreviations of each block are as follows: PAC, Pacific Plate; AMU, Amurian plate; OKH, Okhotsk plate; IZO, Izu-Ogasawara block; TFA, Tohoku Forearc block; TBA, Tohoku Backarc block; and NGT, Niigata block.

observations (Ohzono et al., 2015). In the eastern part of the Philippine Sea Plate, the backarc spreading along the Izu-Ogawawara islands, which is consistent with geological structures, has been suggested by GNSS observations and block modeling (Nishimura, 2011). I set the block boundaries in the overriding blocks on the basis of the tectonic backgrounds described above and divided northeast Japan into 7 rigid blocks for analysis.

I generated a set of subfaults on the subducting Pacific Plate interface along the Kuril

and Japan Trenches and the subducting Izu–Ogasawara block interface along the Sagami Trough based on the plate geometry model compiled by Iwasaki et al. (2015). Triangular meshes were adopted for the subfault because a triangles can express curved surfaces such as subducting plate interfaces more easily than rectangles. The length of the subfault on the plate interface is approximately 20 km. The depth ranges from trench depth to 80 km along the Kuril and Japan Trenches and from trough depth to 60 km along the Sagami Trough. Additionally, I generated triangular subfaults along the inland block boundaries. The dip angle and lower limit of the subfault are 90° and 20 km in depth, respectively.
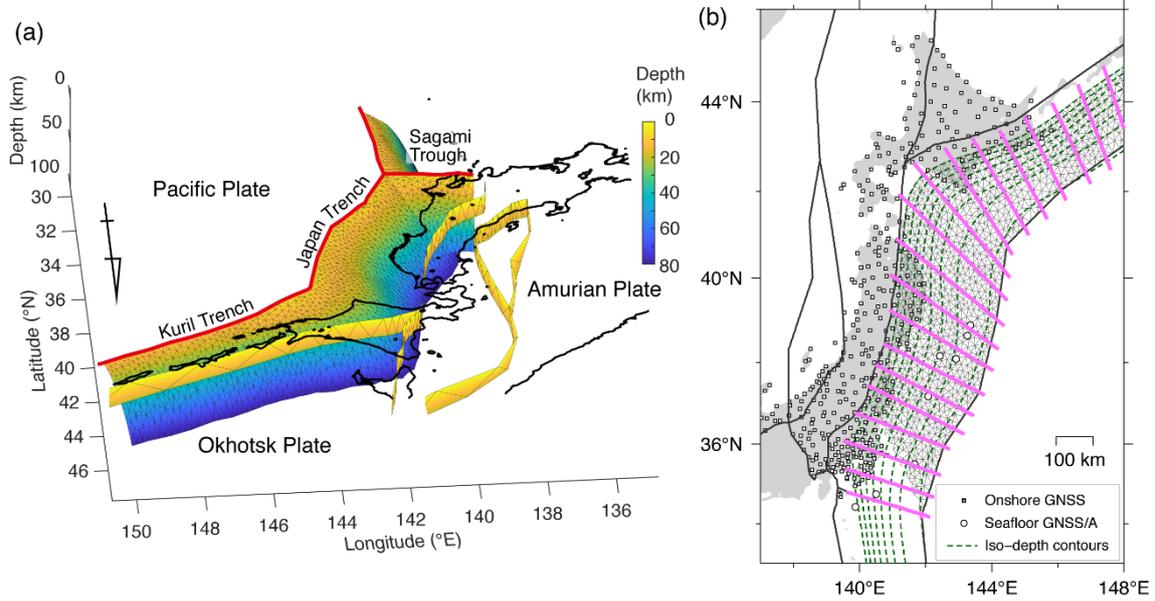

Figure 2.4. Configuration of plate and block interfaces. (a) Three-dimensional map showing the interface of the block and subducting plates, observed from the north-northeast. Triangles on the interface are subfaults. The color scale means the depths. Black lines show the coast lines. (b) Map showing subfaults on the subducting plate interface. Green lines indicate the iso-depth contours of subducting plate interface. z_{up} and z_{down} are sampled along the pink lines.

2.3. Estimated mechanical locking distributions

Figure 2.5 shows the estimated mechanical locking distributions along the Japan and Kuril trenches. The background color scale indicates the locking probability P_l at each subfault l, which is defined as follows:

$$P_l = \frac{N_{l_{Locking}}}{N_{l_{Total}}},\tag{29}$$

where $N_{l_{Total}}$ denotes the number of total sampling, and $N_{l_{Locking}}$ denotes the number of sampling that the subfault l was judged to be mechanically locked. This probability was calculated from all samples of original chain (i.e., chain number = 1 in which $T=1$) except the samples within the burn-in period after the REMC iterations. Additionally, Figure 2.6 shows PDFs of the up- and down-dip depth limits and the locking probability P_l along lines A, B, C, D, E, and F from Figure 2.5. Two separated mechanical locking segments were estimated offshore Miyagi and Fukushima, and one locking zone extending with NE–SW orientation was estimated in eastern Hokkaido along the Kuril Trench.

In the mechanical locking segment extending off eastern Hokkaido, numerous subfaults with low P_l were broadly distributed around the locked subfaults with high P_l. The PDFs exhibit multimodal or flat-shaped peaks (Figure 2.6). The 95 percentile confidence intervals at cross sections A, B, and C were 51 (up-dip in A), 67 (down-dip in A), 40 (up-dip in B), 50 (down-dip in B), 35 (up-dip in C), and 25 km (down-dip in C). Although almost all samples were within the model region depth ranges, more than half of samples of the up-dip depths in lines A and C, almost all samples of the up-dip depths in line B, and some samples of the down-dip depths in line A were outside the model

region depths (i.e., sampled at the depths shallower than trenches or deeper than the bottom). The peaks of the PDF estimated outside of the model region depths indicate that the edge of the model region (trench or bottom) is completely mechanically locked. For example, the trench along line A can be assumed to be mechanically locked. In that case, an exact PDF peak depth does not have a physically important meaning because the mechanical locking states would not change even if the peak depths changed within the depth ranging outside model region depths.

Note that, although there are high P_l zones extending to east of Nemuro, I did not focus on the result in this area because this region is near the boundary of the study area, and poor data coverage hindered the ability to achieve high-resolution and accurate estimates for mechanical locking distributions.

Off northern Tohoku, almost all subfaults exhibit a P_l of ~0 (Figure 2.5). I plotted the PDFs and P_l along lines SA, SB, SC, and SD (Figure 2.7). Almost all samples of the up- and down-dip depths along these lines were observed to intersect. At line SC, the PDFs of both up- and down-dip depths were almost equal, and their 95 percentile confidence intervals were very large.

In the locking segments off Miyagi and Fukushima, there were only some subfaults showing a low P_l around the subfaults with a high P_l. Although there were some possible mechanical locking subfaults between certain segments situated off Miyagi and off Fukushima, the P_l was lower than 0.3. The PDFs of both the up- and down-dip limitation depths had a relatively sharp and unimodal peak along the lines D, E, and F (Figure 2.6d, e, and f). The 95 percentile confidence intervals at these lines were 5 (up-dip in D), 4 (down-dip in D), 9 (up-dip in E), 6 (down-dip in E), 9 (up-dip in F), and 16 km (down-dip in F). These confidence interval values are notably smaller than those in eastern Hokkaido, implying that the resolution of data off Miyagi and Fukushima is much

higher than that off eastern Hokkaido.
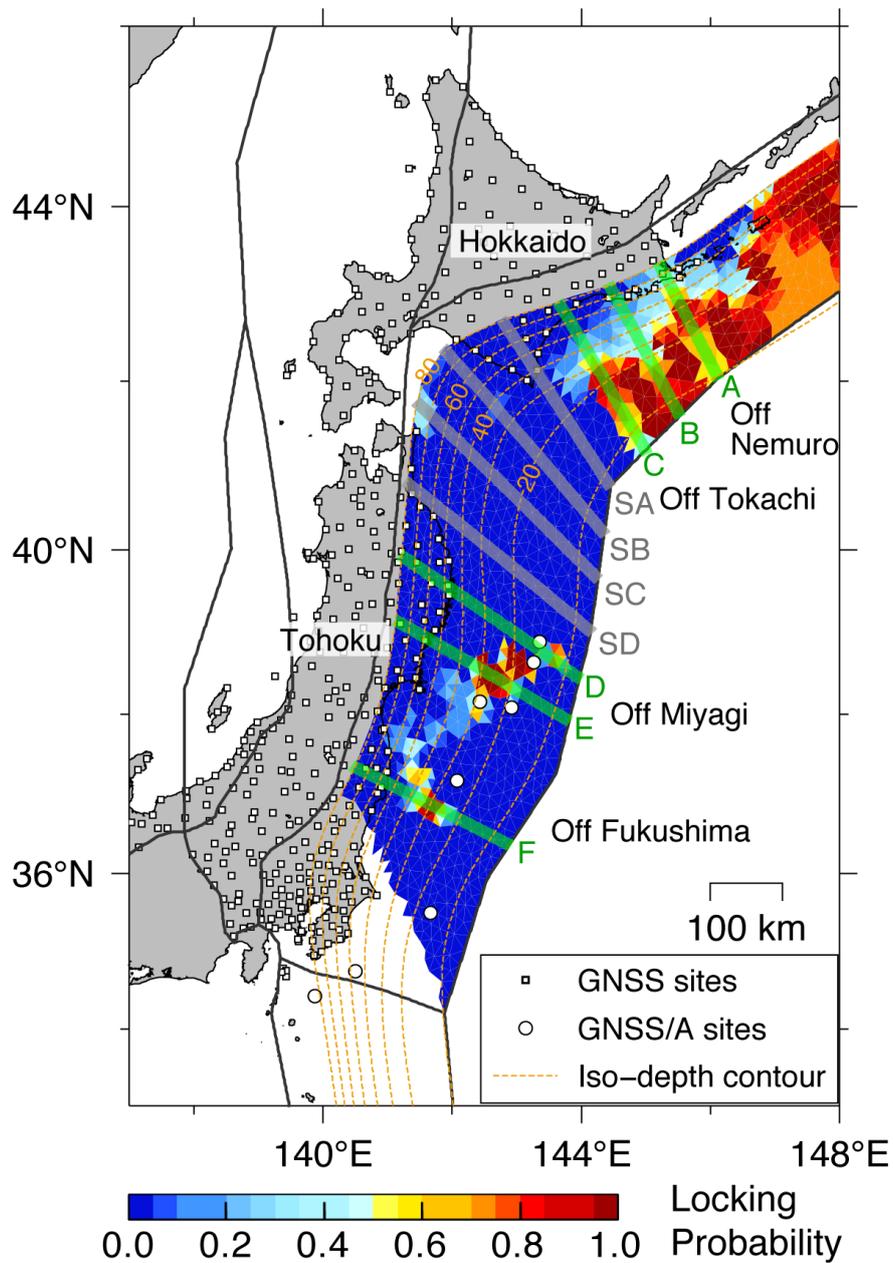

Figure 2.5. Map showing estimated mechanical locking distributions on the plate interface along the Nankai Trough. Color scale indicates the locking probability of each subfault given by Equation (29). Orange dashed lines indicate the iso-depth contours of the subducting plate interface. Black dashed lines indicates the boundary of the plate interface. The lower surface of the overriding Nankai block interfaces with the upper surface of the subducting Philippine Sea Plate to the west and north of the line, whereas it interfaces with the upper surface of the subducting Izu Micro Plate to the east and south of the line.
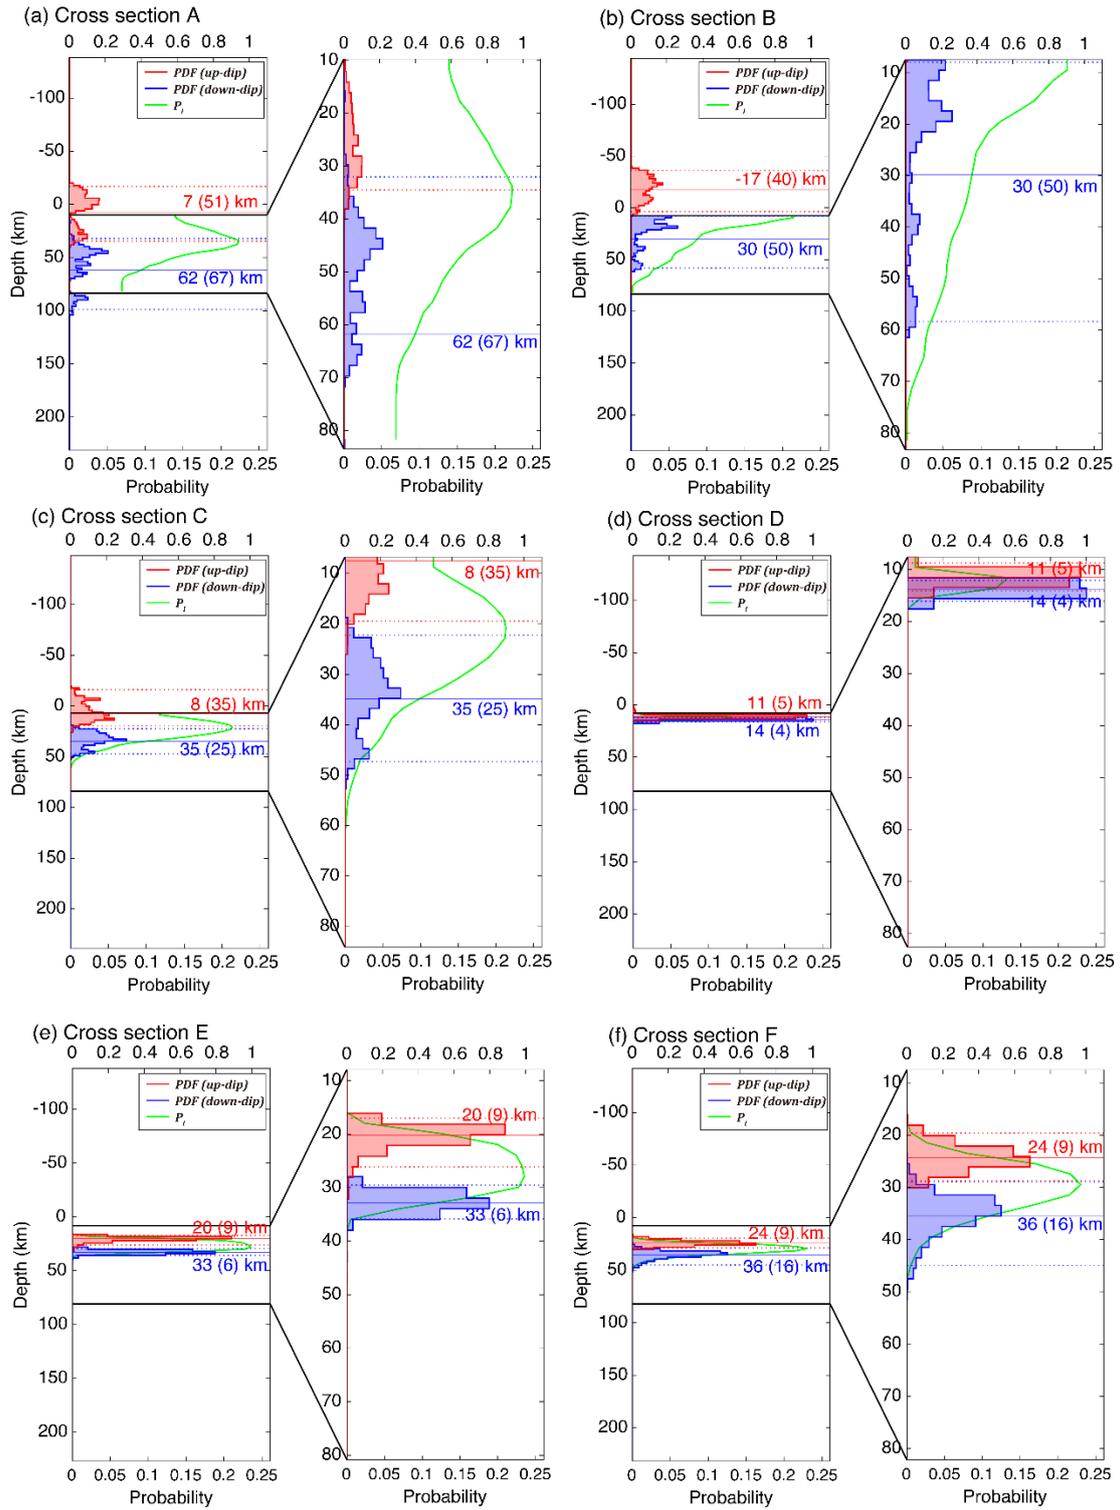

Figure 2.6. Graphs showing PDFs of the up- and down-dip depths and the locking probability P_l along lines A, B, C, D, E, and F in Figure 3.6. For each subfigure, PDFs and the locking probability are plotted for whole sampling depths in the left panels, whereas they are plotted for model area depths (i.e., top and bottom depths coincide with

55

the trench and 60 km depth, respectively) in the right panels. PDFs are normalized such that the sum of the value for each bin becomes 1. Horizontal red and blue solid lines indicate the mean values of the up- and down-dip depths calculated from all samples, respectively. Mean values are described on or under the lines. The 95 percentile confidence interval values are described in brackets to the right of the mean value. The scale of PDFs and locking probability is shown in the bottom and top axes for each panel, respectively.
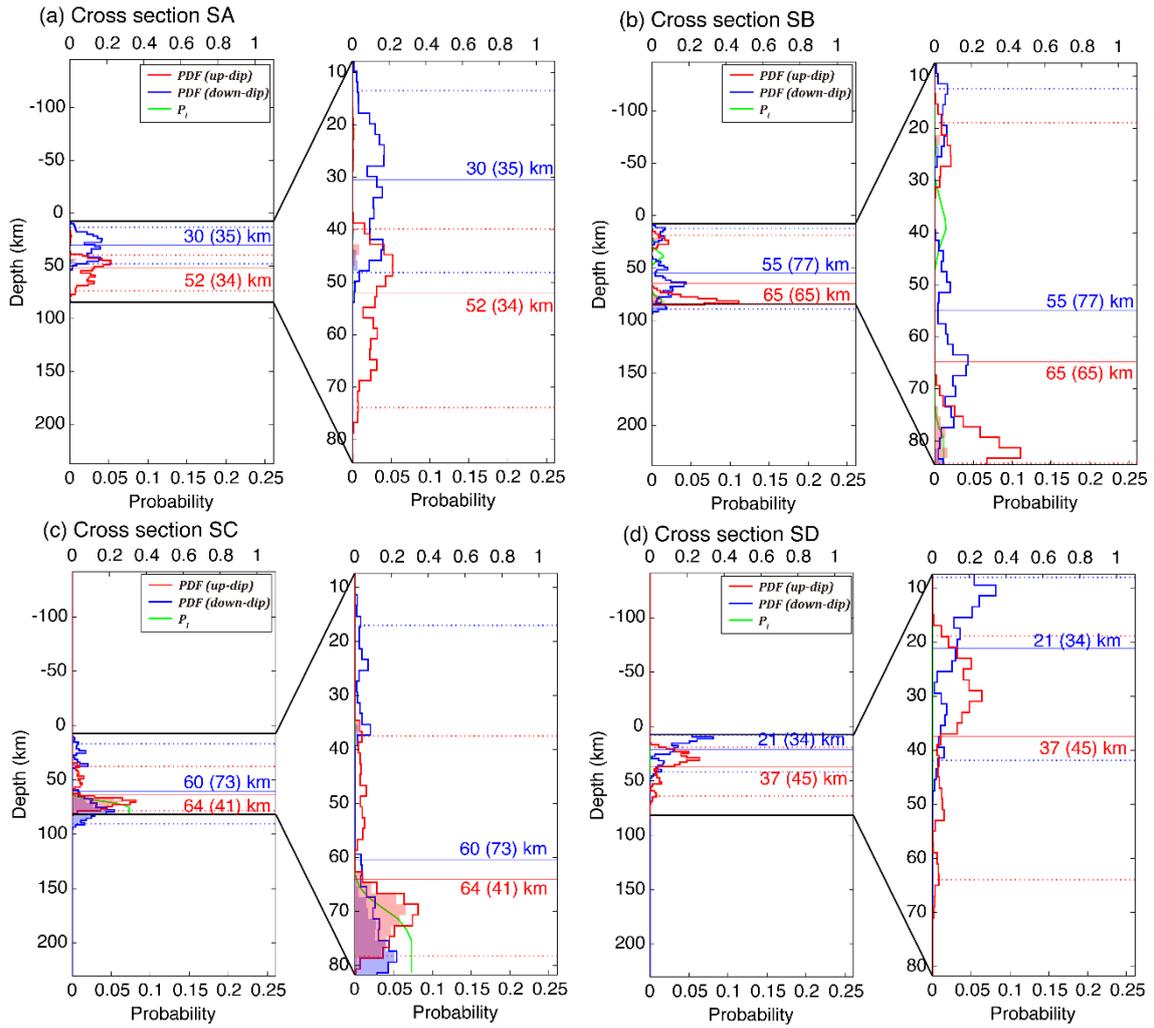

Figure 2.7. Same as Figure 2.6, but along the gray lines SA, SB, SC, and SD in Figure 2.5.

2.4. Discussion

2.4.1. Comparison with kinematic coupling distributions

I compared the estimated mechanical locking distributions with the kinematic coupling distributions estimated in previous studies to reveal the spatial relationship between the two distributions, which were obtained using conceptually distinct models. To calculate the slip deficit rate distribution based on the estimated mechanical locking distribution, I selected the subfaults whose locking probability is larger than 0.5 as comprising the mechanically locked zone (Figure 2.8a). The calculated slip deficit rate distribution is shown in Figure 2.8(b).

The maximum slip deficit rate in the mechanical locking zone is 78 mm/yr off Miyagi and Fukushima. Slip deficits due to the mechanical locking spread to the region that is sufficiently far from the mechanical locking zone, although the slip deficit rate decreases as the distance from the mechanical locking zone increases. The slip deficit rates decrease to 50% of full slip deficit rate (i.e., ~40 mm/yr) at ~35 km from the locking zone off Miyagi and ~15 km from the locking zone off Fukushima. At the region that is ~100 km north from the locking zone off Miyagi, 20% of the full slip deficit rate (i.e., ~17 mm/yr) remained. Between the locking zones off Miyagi and Fukushima, the slip deficit rate was maintained at over 20 mm/yr. This implies that slip deficits decay gradually from mechanical locking zones if the distance of multiple locking segments is small, as suggested by Herman et al. (2018).

The mechanical locking distribution off Tokachi roughly overlaps the high slip deficit rate areas estimated by previous studies (Hashimoto et al., 2012; Loveless & Meade, 2010, 2015; Suwa et al., 2006). However, the mechanically locked zones estimated in this study tended to be smaller than areas where the high slip deficit rates were estimated by previous studies. The maximum slip deficit rate is 76 mm/yr in mechanical locking zones

along the Kuril Trench. Although high slip deficit rate areas were reported to extend southwest off Tokachi to the northernmost part of Tohoku in some studies (Hashimoto et al., 2012; Loveless & Meade, 2015; Suwa et al., 2006), low or almost zero P_l values were observed in this study (Figure 2.5). I found that the slip deficit rate spreads from the mechanical locking zone off Tokachi and maintains approximately 25% of the full slip deficit rate (i.e., ~20 mm/yr) at a region that is ~95 km west from the locking zone.

At the region off Miyagi and Fukushima, this study estimated two clearly separated locking zones in these regions, unlike the one larger high-slip deficit rate area (Loveless & Meade, 2010, 2015; Suwa et al., 2006) or two vaguely separated high-slip deficit rate areas (Hashimoto et al., 2012) with very smooth gradients that were estimated in previous studies. Although Hashimoto et al. (2012) estimated the highest slip deficit rate roughly in the same region where this study estimated the mechanical locking, it was impossible to identify mechanical locking regions because the slip deficit rate is simply a kinematic value that does not indicate mechanical locking states. However, by developing and adopting a new physical model that prescribes mechanical locking states by imposing a mechanical constraint, I confirmed the regions that Hashimoto et al. (2012) estimated the highest slip deficit rate as appearing mechanically locked. The detailed positions where Hashimoto et al. (2012) estimated the highest slip deficit rate and where mechanical locking was identified by this study are slightly different. For example, the mechanical locking zone off Fukushima was estimated at the region that is ~50 km landward side of the region where Hashimoto et al. (2012) estimated the highest slip deficit rate off Fukushima. Moreover, this study estimated a mechanical locking zone whose up-dip limit extends to ~10 km in depth off Miyagi, whereas the up-dip limit of the highest slip deficit rate estimated by Hashimoto et al. (2012) is ~20 km in depth. This slight difference may be caused by using the seafloor GNSS/A in this study. Seafloor GNSS/A data may have

enhanced the resolution power in offshore areas where the mechanical locking or high slip deficit rate were estimated.

From the comparison outlined in this chapter, it was expected that the mechanical locking zones would be estimated to be included in the kinematic high-coupled zones, and the size of the mechanical locking zone would be smaller than that of the kinematic high-coupled zone when estimating mechanical locking distributions using the proposed model with interseismic geodetic observation data. Thus, even if high slip deficit rate was estimated at the wide area based on the pure kinematic model, the mechanically locked zone may only encompass a portion of the total area.
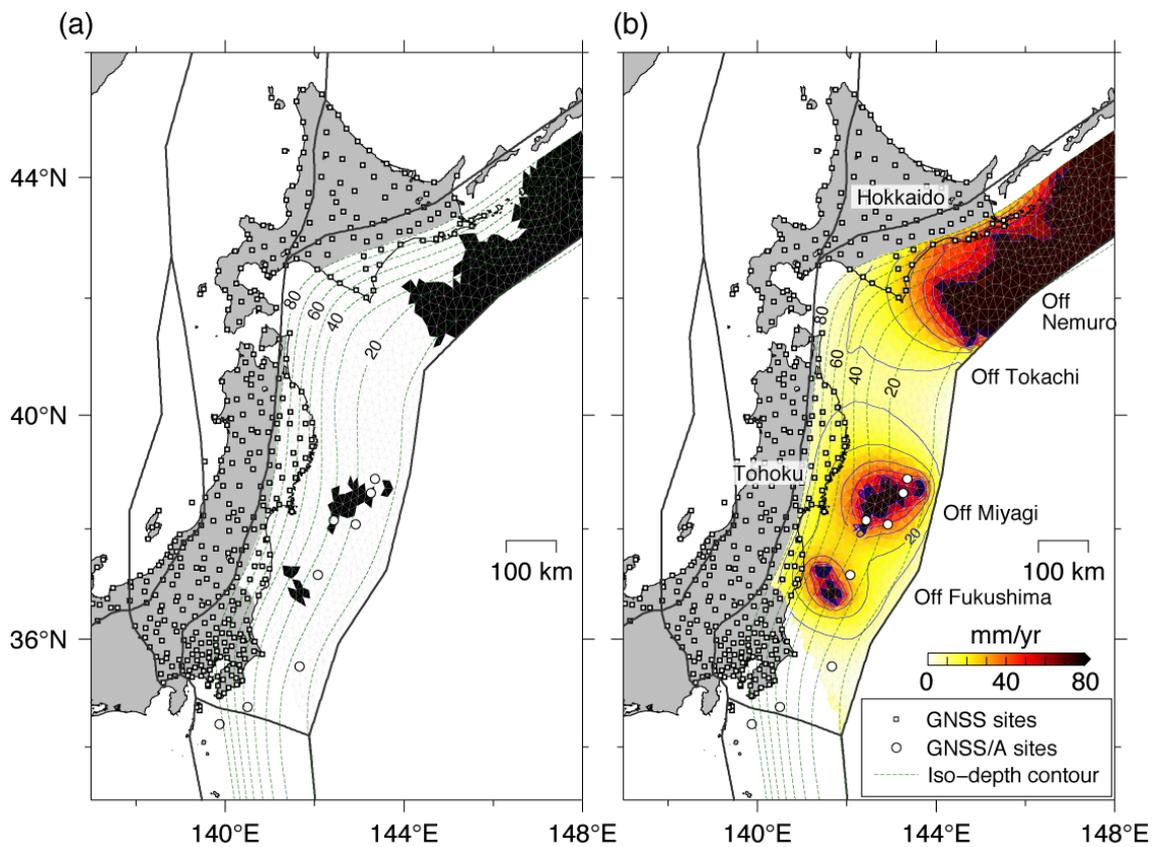

Figure 2.8. Calculated slip deficit rate distributions along the Kuril and Japan Trenches. (a) To calculate the slip deficit rate distribution, subfaults whose locking probability is larger than 0.5 (Figure 2.5) were selected to be the mechanically locked zone. The selected subfaults are denoted in black. (b) Map showing the slip deficit rate distributions derived from the locking distributions shown in (a). Blue lines indicate the slip deficit rate contours with an interval of 10 mm/yr, starting from 10 mm/yr.

2.4.2. Correspondence with interplate earthquakes

In 2011, a *Mw* 9.0 Tohoku Earthquake occurred off Miyagi, and its coseismic slip propagated through an extremely wide area that extended near Fukushima. The coseismic rupture began at the southern edge of the mechanical locking zone off Miyagi estimated in this study (Figure 2.9). Some previous studies estimated the coseismic slip distributions and thus released a seismic moment of 4.0×10^{22}–4.2×10^{22} Nm from the geodetic observation data (e.g., Iinuma et al., 2012; Ito et al., 2011; Yokota et al., 2011). The subfaults located off Miyagi and Fukushima and those whose locking probability was larger than 0.5 were selected as mechanical locking zones. Their areas were 5.10×10^3 km^2 (off Miyagi segment) and 1.99×10^3 km^2 (off Fukushima segment). These two mechanical locking segments are considered to comprise the rupture zone of the 2011 Tohoku Earthquake. Based on these two locking segments and assuming the peak coseismic slip magnitude estimated by Yokota et al. (2011) (~35 m in the segment off Miyagi and ~10 m in the segment off Fukushima) and the uniform rigidity value of 40 GPa, the possible total released seismic moment was calculated to be 7.94×10^{21} Nm. This value is only 19% of that estimated by previous studies (e.g., Iinuma et al., 2012; Ito et al., 2011; Yokota et al., 2011). Because the coseismic distributions by previous studies differ, I evaluated another scenario in which ~60 m of slip magnitude, equivalent to the maximum slip magnitude (Iinuma et al., 2012; Ito et al., 2011; Sun et al., 2017), was imposed at the rupture zone. However, the released seismic moment was calculated to be 1.30×10^{22} Nm, which is only 32% of the moment estimated by previous studies. The remaining moment would be released by the slip of areas that surround the mechanical locking zones wherein the slip deficit is accumulated during interseismic periods. This implies the possibility that the areas subjected to significant mechanical rupture during seismic events are considerably smaller than areas that release the entire seismic moment.

Rupture at the mechanical locking zone can release only 20–30% of the total moment. The remaining 70–80% of the moment would be released by the slip of the region outside of the mechanical locking zone accompanied by the rupture of mechanical locking zone.

To assess the total moment release due to total coseismic slip (i.e., rupture of the mechanical locking zone and accompanying slip outside the locking zone), simple coseismic slip simulations were conducted (Figure 2.10). In the simulation, slip was imposed only at mechanical locking zones off Miyagi and Fukushima; then, the total slip including that around the mechanical locking zone and surface responses (displacements) were calculated. The imposed slip magnitude in the locking segments were evaluated at ~35 m in the segment off Miyagi and ~10 m in the segment off Fukushima, following the estimates of Yokota et al. (2011). To calculate surface displacement, only the elastic response from the total coseismic slip was considered by assuming the constant strain states on the area outside the mechanical locking zone (i.e., the region where the slip was imposed). The simulation indicated that the coseismic slip propagated to both landward and trenchward sides (Figure 2.10(b)). However, the extremely large slip at the trench, which is sometimes called the "overshoot" and considered to be generated by dynamical rupture processes (e.g., Fukuyama & Hok, 2015; Ide et al., 2011), was not obtained because this study did not consider factors that can affect dynamical rupture processes (e.g., frictional strength or three-dimensional shape of locking zones), and coseismic slip was only calculated to satisfy the constant strain states on the plate interface outside the mechanical locking zones. The coseismic slip outside the rupture area reached regions over 100 km from the rupture area off Miyagi, whereas it reached regions 30–40 km from the rupture area off Fukushima. This occurred because the size of the rupture area off Fukushima was smaller than that observed off Miyagi, and the given slip magnitude off Fukushima was only a quarter of that observed off Miyagi. The coseismically released

moment calculated on the basis of the slip distributions was 4.68×10^{22} Nm. Although the estimated moment value is 17% larger than the moment release estimated by Yokota et al. (2011), this difference is not significant considering data and model uncertainties. Calculated displacements are clearly larger than the observed displacements (JPL and Caltech, 2011), specifically in coastal areas of Miyagi and northern Tohoku, although the average calculated displacements at the seafloor sites were roughly equivalent to the observed displacements (Figure 2.10(c)). This may have been caused by the larger slip in this simulation compared to the actual coseismic slip at the landward side of the rupture area off Miyagi. Coseismic slip distributions inverted from the geodetic, seismic, or tsunami observation data show spatial heterogeneity (e.g., Iinuma et al., 2012; Simons et al., 2011; Yokota et al., 2011), which differs from the radial-like slip distribution simulated above. Furthermore, the postseismic slips were estimated on the plate interface where the coseismic slip was relatively smaller, such as that observed at the landward side of the rupture area (e.g., Iinuma et al., 2016; Figure 2.9). The over slip calculated at the landward side of the rupture area (Figure 2.10(b)) can be partially explained by the postseismic slip.

Near the southern tip of Hokkaido, the 2003 Tokachi Earthquake occurred (Figure 2.9). The coseismic rupture began from the southwestern edge of the mechanical locking zone along the Kuril Trench estimated in this study. Based on the teleseismic wave analysis, the coseismic slip area of the earthquake, with a ~100 km width, was estimated to be north of the hypocenter (Yamanaka & Kikuchi, 2003). The seismic moment released by the earthquake was estimated to be in the range of $1.0 \times 10^{21} – 1.7 \times 10^{21}$ Nm, from the seismic observation data (Yagi, 2004; Yamanaka & Kikuchi, 2003). In addition to the 2003 Tokachi Earthquake, an *Mw* 8.3 earthquake occurred in 1952 in Tokachi. The earthquake rupture area was also estimated in roughly the same location as that of the 2003 Tokachi

earthquake. The study estimated an extremely large mechanical locking zone along the Kuril Trench, while the southwestern portion overlapped with the southeastern portion of the coseismic slip area of the 2003 Tokachi Earthquake. Seismic rupture from this earthquake started from the southeasternmost part of the coseismic slip zone (i.e., the western edge of the estimated mechanical locking zone along the Kuril Trench) and propagated northward to the down-dip side (Robinson & Cheung, 2010; Yagi, 2004) where the mechanical locking zone was not estimated in this study. A simple coseismic slip simulation for the 2003 Tokachi Earthquake, based on the mechanical locking distribution estimated in this study, was attempted. The mechanical locking zone where the coseismic slip area of the earthquake overlapped the rupture area. Then, a slip of ~5 m was imposed in this area (Figure 2.11(a)). As a consequence, the coseismic slip propagated concentrically around the rupture area. A slip of ~1 m reached a distance of ~55 km from the rupture area (Figure 2.11 (a)). 2.41×10^{21} Nm of moment release was calculated. The simulated moment was 50–92% larger than that estimated by previous studies (Yagi, 2004; Yamanaka & Kikuchi, 2003). This implies that the actual size of the rupture area of the 2003 Tokachi Earthquake may be much smaller than that of the rupture area assumed in the simulation. Predicted surface displacements moved in an eastward direction compared to the observed coseismic displacements (Larson & Miyazaki, 2008; Figure 2.11 (c)), and they were larger than those observed at the tip of Tokachi and smaller than those observed at the coastal area of east of Tokachi. This difference suggests that to the west (or W-NW direction) of the locking zone along the Kuril Trench, there may be hidden mechanical locking zones that could not be estimated from the geodetic observation data used in this study. Additionally, the hidden locking zones may be distributed in pieces and may be extremely small because the small coseismic slip areas with several remarkable slip peaks were estimated to extend

westward (Yagi, 2004; Yamanaka & Kikuchi, 2003), where no mechanical locking zone was estimated in this study. Developing a considerably denser geodetic observation network may enable the estimation of complex mechanical locking distribution, such as the small-scattering mechanical locking zones.

Interplate earthquakes with magnitudes of 7–8 have occurred frequently off northern Tohoku (Yamanaka & Kikuchi, 2004). However, a low or almost zero P_l value was observed, thereby leading to extremely low slip deficit rates in this area. Some previous studies as well as the present analysis that used geodetic inversion revealed a relatively low slip deficit rate in this region compared to that in other regions, such as off Tohoku and off eastern Hokkaido (Hashimoto et al., 2012; Suwa et al., 2006). One possible reason for the occurrence of interplate earthquakes with a $> M$ 7 in this region, where no mechanical locking zones (or low slip deficit rate in previous studies) were estimated owing to poor resolution due to no offshore geodetic observation data, is that extremely small locking zones were scattered in this region. The 2011 Tohoku Earthquake could be explained by the two small mechanical locking zones located near Miyagi and Fukushima, as discussed above. If a single rupture at the Miyagi locking segment is assumed, the released moment magnitude could be $Mw > 8.5$ because the released moment in the off Fukushima segment might be sufficiently less than that at the off Miyagi segment. Thus, possible mechanical locking zones explaining the occurrence of M 7–8 earthquakes may be much smaller than those estimated at the Miyagi and Fukushima segments. The crustal deformations due to the small mechanical locking zones located beneath the seafloor may not be detected as clear signals with onshore geodetic observations. It is important to estimate small mechanical locking zones because the simultaneous rupturing of multiple mechanical locking zones can lead to the huge seismic moment releasing, even if each mechanical locking zone is small (Herman et al., 2018). It is possible to detect small

mechanical locking zones by developing a denser and more accurate geodetic observation network on the seafloor as well as onshore.

The mechanical locking zone estimated along the Kuril Trench extends northeastward to regions situated off Nemuro. Many large interplate earthquakes have occurred along the Kuril islands (Fukao & Furumoto, 1979). Coseismic slip models of these earthquakes were estimated by seismic waveform inversions (Yamanaka, 2005) and tsunami waveform inversions (e.g., Satake et al., 2008; Tanioka et al., 2013). One notable recent event is the M 7.8 Nemuro earthquake, which occurred in 1973 (Figure 2.9). Although this area was not evaluated in detail owing to the lack of high-resolution data, the results show large mechanical locking zones and accompanying high-slip deficit rates along the Kuril Trench extending northeastward, which may imply the occurrence potential of middle-large sized interplate earthquakes and their huge counterparts that occur by rupturing the multiple mechanical locking segments, as suggested by The Headquarters for Earthquake Research Promotion (2017).
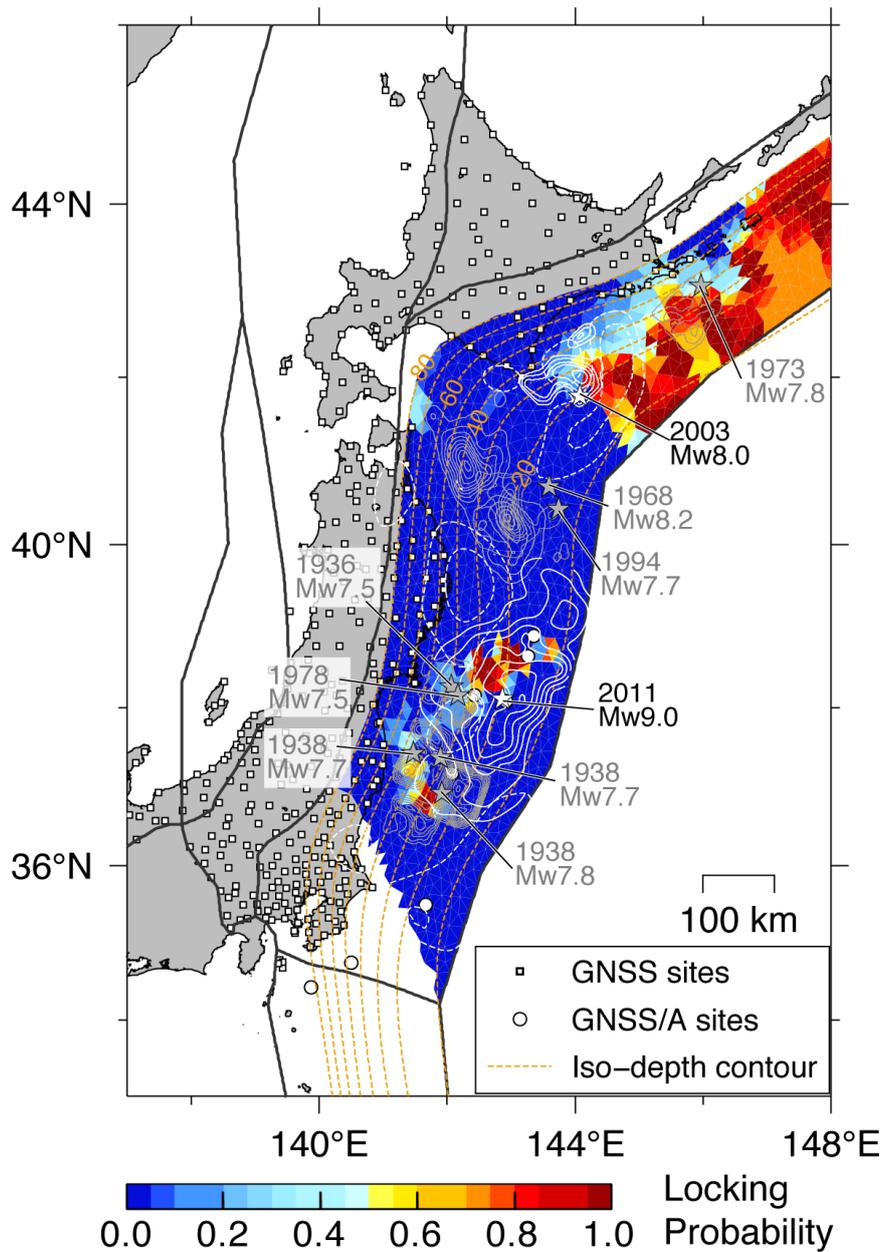

Figure 2.9. Map showing the spatial relationship between mechanical locking distributions, coseismic slips, and postseismic slips. White solid lines indicate the coseismic slip contours of the *Mw* 8.0 Tokachi earthquake in 2003 (Yamanaka & Kikuchi, 2003) and *Mw* 9.0 Tohoku earthquake in 2011 (Iinuma et al., 2012). White dashed lines indicate the postseismic slip contours of the *Mw* 8.0 Tokachi earthquake in 2003 (Miyazaki et al., 2004) and *Mw* 9.0 Tohoku earthquake in 2011 (Iinuma et al., 2016). Red stars indicate the epicenters of the two earthquakes. Gray solid lines indicate the coseismic slip contours of other interplate earthquakes occurring in northeast Japan (Murotani et al., 2003; Nagai et al., 2001; Yamanaka, 2005).

The red areas were defined as the coseismic rupture (brittle rupture) areas, and only the coseismic slip in these areas was given. The slip magnitude provided in the simulation is 5 m in the coseismic rupture area. As same as the case of the coseismic slip simulation of the 2011 Tohoku earthquake, only the constant strain condition was considered on the possible slip area (blue area), and any other constraints or boundary conditions were not adopted for the slip behavior on the blue area. (b) Map showing the total coseismic slip on the plate interface. Blue lines indicate slip contours with an interval of 1 m. (c) Map showing the surface displacements as the response of the total slip on the plate interface at the onshore and seafloor sites used in this study. Red-enclosed white arrows indicate the calculated displacements. Black arrows indicate the observed coseismic displacements (Larson & Miyazaki, 2008).

2.4.3. Comparison with strong motion generation areas

Large earthquakes can generate seismic waves causing a strong ground motion. The radiation source of the seismic wave causing strong ground motions is called strong motion generation area (SMGA; e.g., Miyake et al., 2003). Because strong ground motion can cause significant damage, mainly to infrastructure (Kanda et al., 2004; Kawase, 1998; Nozu et al., 2012), it is important to reveal the spatial relationship between mechanical locking distributions and SMGAs for earthquake disaster prevention and mitigation efforts.

Figure 2.12 shows the SMGAs of the 2003 Tokachi Earthquake and 2011 Tohoku Earthquake. The 2003 Tokachi Earthquake was the first interplate earthquake observed by K-net and KiK-net, which are dense strong motion seismogram networks (Aoi et al., 2000; Kinoshita, 1998). The 2011 Tohoku Earthquake was the largest interplate earthquake recorded by these networks. In the Tohoku region, most SMGAs were located near the edges of the mechanical locking zones estimated in this study. Furthermore, most SMGAs tend to be concentrated at the down-dip side of the mechanical locking zones. Some SMGAs are distributed some distance away from the edges of the mechanical locking zones. However, considering the estimation errors of the mechanical locking distributions near Fukushima, most are likely also located at the edges of the mechanical locking zones. Near Tokachi, half of the SMGAs were located near the edge of the mechanical locking zone. The other half were located approximately 50–70 km west and north of the mechanical locking zone. As discussed in Chapter 2.4.2, there may be small, hidden mechanical locking zones to the west (or WNW) of the estimated mechanical locking zones along the Kuril Trench. Hence, the SMGAs located approximately 50–70 km west and north of the mechanical locking zone estimated along the Kuril Trench may be related to the hidden mechanical locking zones, although this supposition was not provable in this study.

From the comparisons presented above, it is expected that SMGA candidates for megathrust earthquakes can be predicted from mechanical locking distributions estimated from interseismic geodetic observation data using the proposed model. There may be a predictable limitation depending on the size of mechanical locking zones. As in the case of Tokachi, although the possible seismic moment released by the earthquake is sufficiently large (i.e., $M \geq 8$), SMGA candidates are not predictable if the mechanical locking zones cannot be estimated owing to the poor resolution.

71
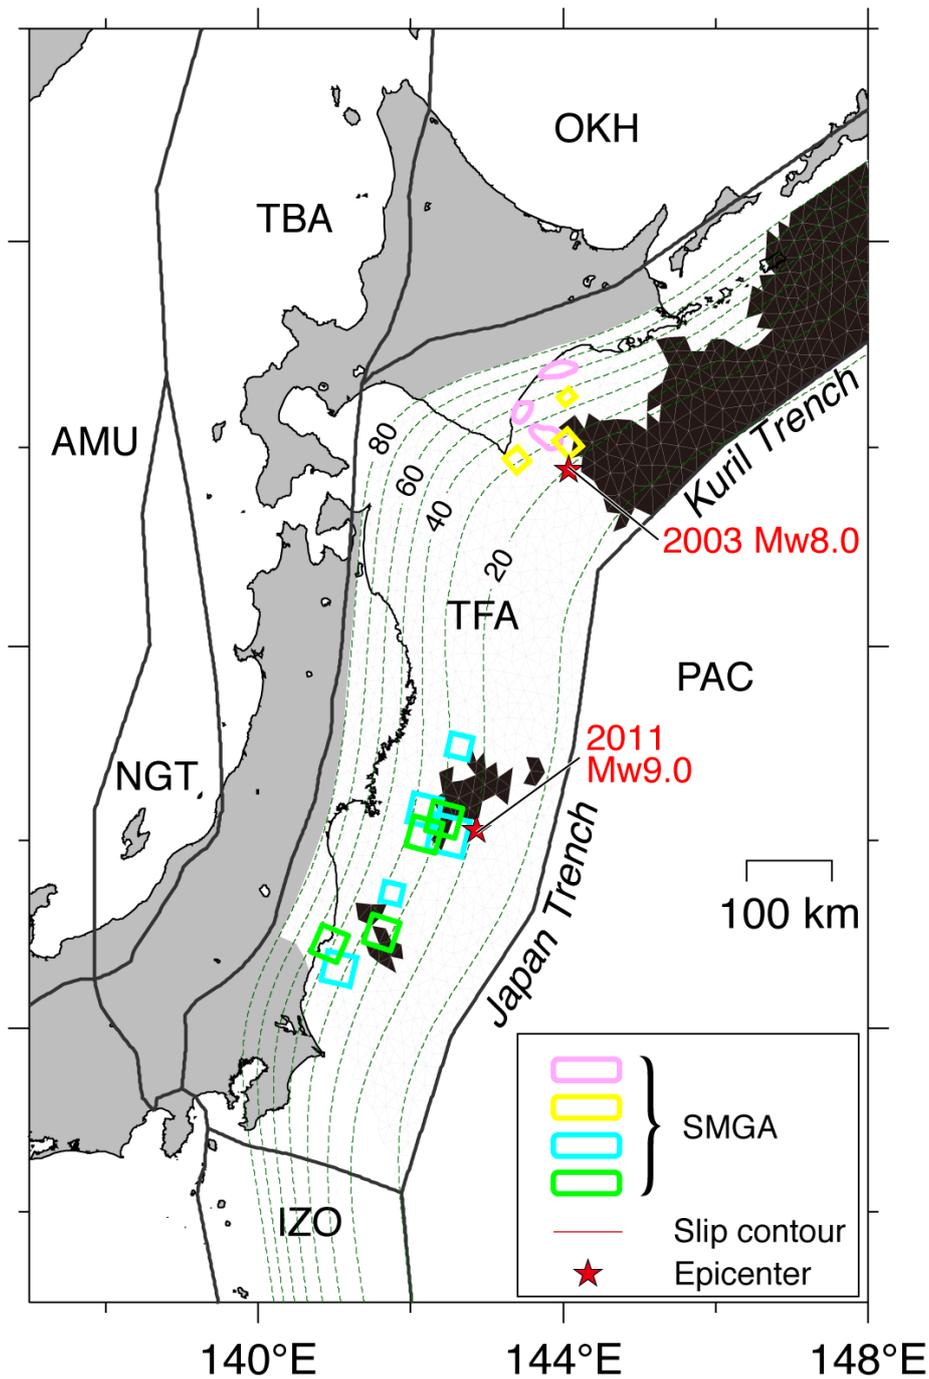

Figure 2.12. Map showing the spatial relationship between mechanical locking zones and SMGAs. Black meshes indicate the estimated mechanical locking zone shown in Figure 2.8(a). Pink and yellow closed lines indicate the SMGAs of the *Mw* 8.0 earthquake in 2003 estimated by Nozu & Irikura (2008) and Kamae & Kawabe (2004), respectively. Cyan and green closed lines indicate the SMGAs of the *Mw* 9.0 earthquake in 2011 estimated by Kurahashi & Irikura (2013) and Asano & Iwata (2012). Red stars indicate the epicenters of the two earthquakes.

72

2.4.4. Effects of plate interface geometries

The plate interface geometry at the Kuril and Japan trenches used in this study was taken from Iwasaki et al. (2015). Several plate geometry models of the Kuril and Japan Trench subduction zones exist (Hashimoto et al., 2004; Hayes et al., 2018; Hirose et al., 2008; Kita et al., 2010; Nakajima et al., 2009; Nakajima & Hasegawa, 2006), and plate geometry is considered a central factor affecting mechanical locking estimation. To verify this, mechanical locking distributions were estimated using two plate geometry models: "Model I" (Iwasaki et al., 2015) and "Model H" (Hirose et al., 2008; Kita et al., 2010; Nakajima et al., 2009; Nakajima & Hasegawa, 2006). The plate geometry comparison is shown in Figure 2.13(a). Although large geometries are almost equivalent between the models, there are some small-scale difference in the geometry as follows: the depths of the plate interface are deeper for Model H than that for Model I at depths shallower than 20 km; clear unevenness off southern Hokkaido was observed for Model H, whereas the iso-depth contours are smooth for Model I.

Estimated mechanical locking distributions using the two geometries are shown in Figure 2.13(b and c). The locking distributions off Tohoku and Hokkaido were fairly similar to those estimated using Model I. Although there are slight differences in the shape or location of the estimated mechanical locking along the Kuril Trench, these differences are negligible considering the resolution.

The comparison indicates that differences in plate interface geometries do not affect the estimation of mechanical locking distributions if the difference in plate interface geometry is significant, such as those between Model H and Model I. In other words, to reduce the uncertainties of estimated mechanical locking distributions owing to uncertainties of plate interface geometries, it may be required to apply well-determined plate interface geometries such as subduction zones in and around Japan. Thus, enhancing

the geodetic observation network, developing a more realistic physical model describing crustal deformation, and determining the accurate geometries of plate interfaces by robust and accurate geophysical surveys may be useful for reducing estimation uncertainty for mechanical locking distributions.
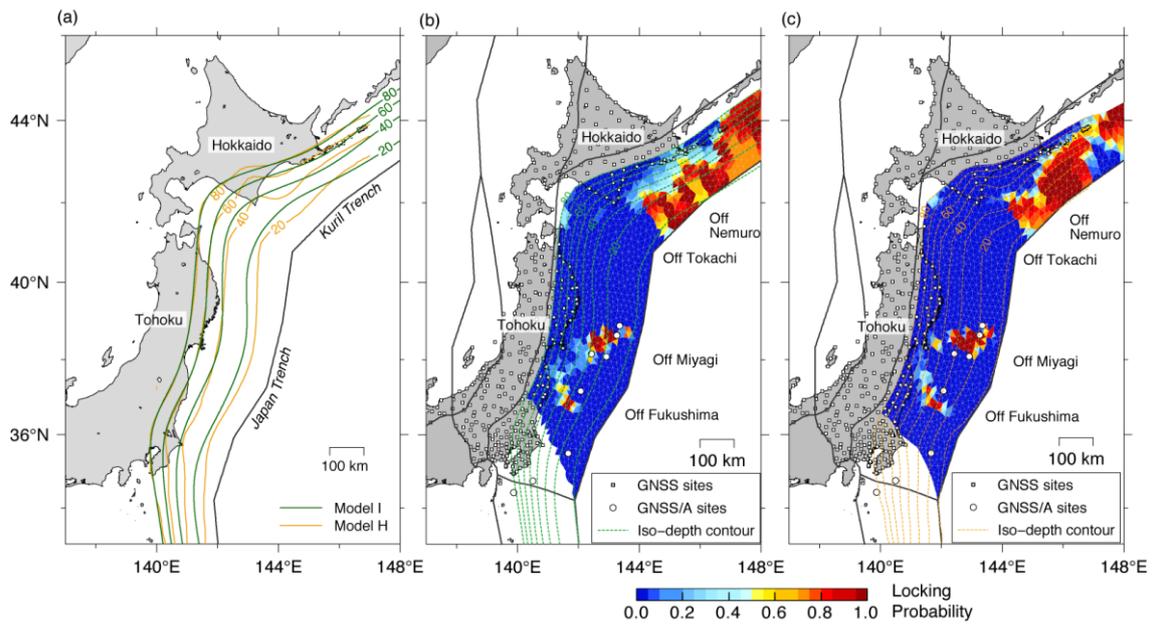

Figure 2.13. Comparison of mechanical locking distributions between two plate geometry models. (a) Map showing iso-depth contours of "Model I" (green lines; Iwasaki et al., 2015) and "Model H" (orange lines; Hirose et al., 2008; Kita et al., 2010; Nakajima et al., 2009; Nakajima & Hasegawa, 2006). The contour interval is 20 km in depth. (b) Map showing the mechanical locking distributions expressed as the locking probability estimated using Model I. (c) Same as (b) but using Model H.

2.4.5. Effects of block division models

The block division model used in this analysis contains 7 rigid blocks (Chapter 2.2.4). To test how simplifying the block division configuration affected mechanical locking distribution estimates, an additional block division model was developed (Figure 2.14). The additional block division model, "Model S," contains 4 rigid blocks and is roughly equivalent to the PB2003 model (Bird, 2003; Figure 2.14b and d). Hereinafter, the original block division model used in the main analysis is called "Model O" for convenience.

The estimated mechanical locking distributions of Models O and S are shown in Figure 2.14(a) and (b), respectively. Two mechanically locked segments were estimated in the Miyagi and Fukushima regions in Model S. The locations and sizes of these locking segments in Model S were almost equal to that of locking segments offshore Miyagi and Fukushima estimated in Model O. One mechanically locked segment was estimated at the region off eastern Hokkaido. While the detailed location and size of the locking segment in Model S differed slightly from that of the locking segment in the region offshore eastern Hokkaido estimated in Model O, particularly at the easternmost part of off Nemuro, this disagreement is negligible if considering the low-resolution data available. Hence, Models O and S produce similar mechanical locking distributions. Regarding the residuals, differences between observed and calculated surface displacement rates in Model S were relatively larger than that estimated in Model O (Figure 2.14c and d). Particularly, there are notably larger and systematic residuals in Nemuro and Niigata in Model S, whereas almost no large and systematic residuals exist in Nemuro and Niigata in Model O. These residuals in Model S seem to vanish at the region where block boundaries were set in Model O (i.e., block boundaries between Niigata and Tohoku-backarc blocks and between Tohoku-forearc block and Okhotsk

plate). Thus, these residuals may have been caused by block configurations and imply the requirement of additional block boundaries in Model S, such as those set in Model O. The estimated mechanical locking distributions might have been biased if the rigid motion could not be distinguished from crustal deformation (i.e., if there are systematic residuals due to inappropriate block configurations). Thus, there is a possibility that the estimated mechanical locking distributions in Model S was biased owing to the lack of block boundaries, although the mechanical locking distributions estimated in Model S was similar to that estimated in Model O. As a consequence, Model O is considered to exhibit better performance than Model S.
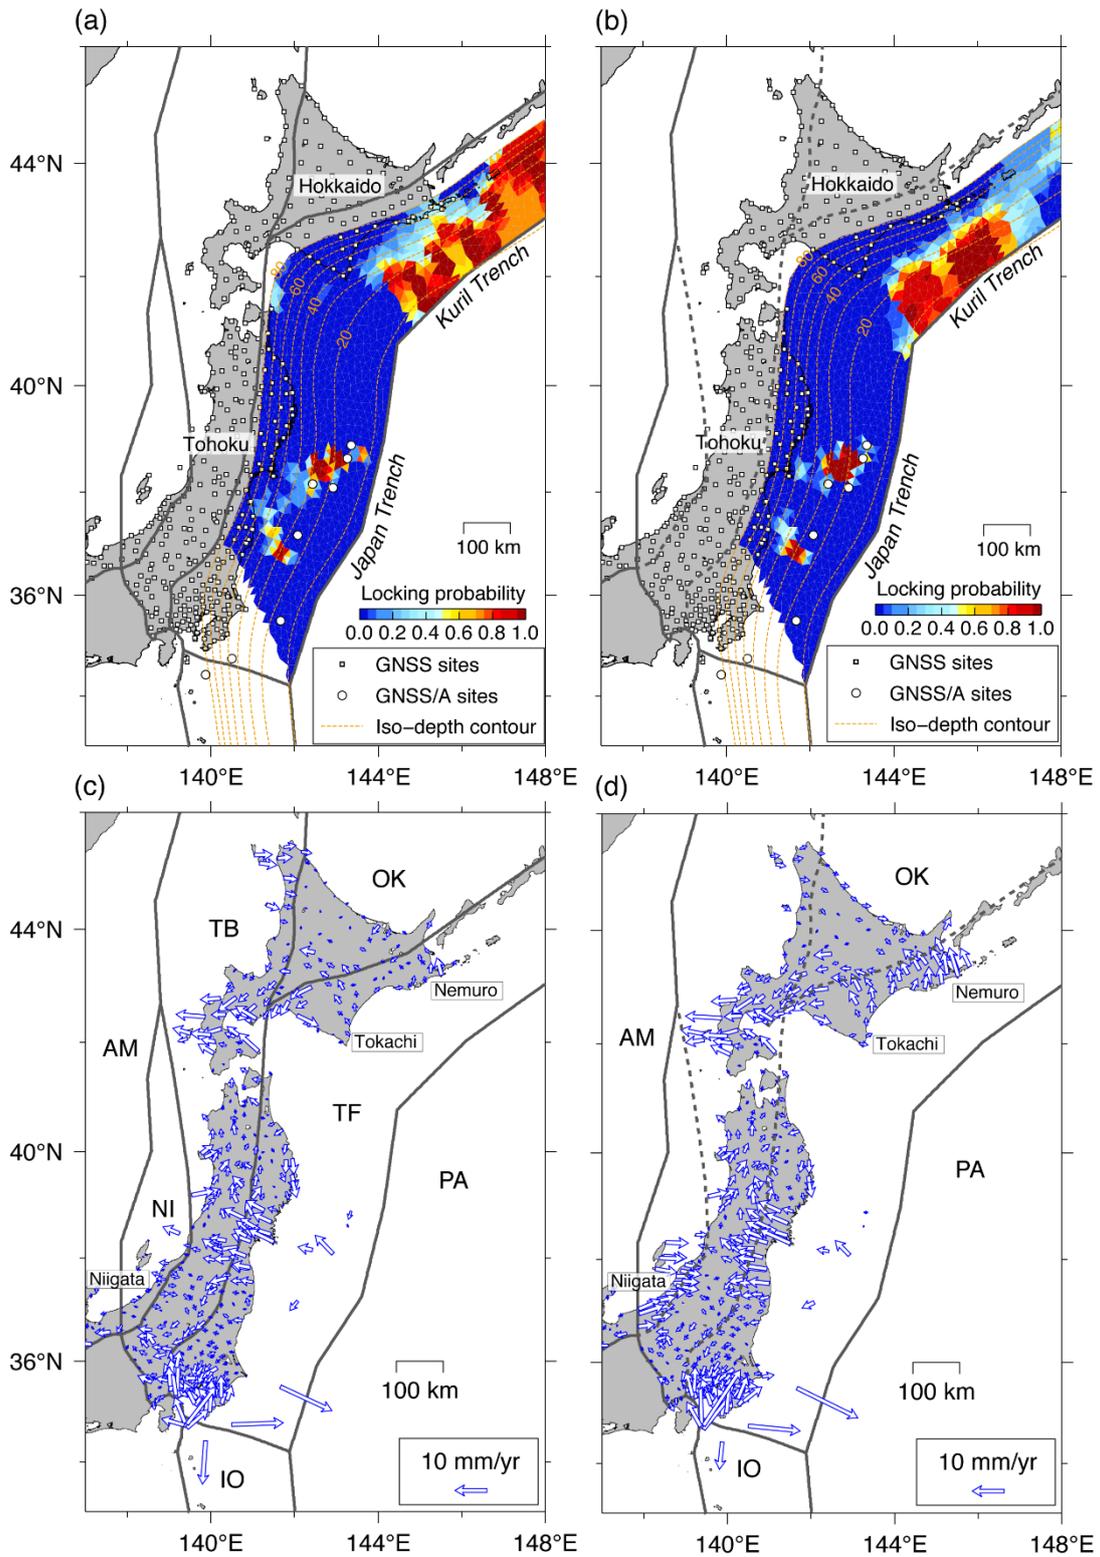

Figure 2.14. Comparison of mechanical locking distributions and residual vectors for Models O and S. (a) Map showing the mechanical locking distributions estimated in

Model O, which is the original block division model used in the main analyses and contains 7 blocks. Background color scale indicates the locking probability. Gray solid lines indicate block boundaries. (b) Same as (a) but for Model S, which is an additional block division model and contains 4 blocks. Gray dashed lines indicate the block boundaries existing in Model O but not in Model S. (c) Map showing residual vectors between observed and calculated displacement rates (observation minus calculation) for Model O. (d) Same as (c) but for Model S.

2.5. Chapter summary

The proposed model, which relates mechanical locking on the plate interface and surface crustal deformation, was discussed in this chapter. This model was applied to northeast Japan to estimate mechanical locking distributions along the Japan and Kuril Trenches based on the onshore and seafloor geodetic observation data by incorporating the REMC method.

Estimated mechanical locking distributions were compared with coseismic (postseismic) slip distributions, hypocenters, and SMGAs of the 2003 Tokachi Earthquake and 2001 Tohoku Earthquake. After comparison, the following conclusions were obtained.

- The mechanical locking zones were estimated in the region where high slip deficit rates were estimated by pure kinematic model in previous studies. Slip deficits accompanied by mechanical locking can explain the high-slip deficit rates estimated by previous studies in regions where creeping was estimated without estimated mechanical locking in this study.

- The mechanical locking zone is notably smaller than total coseismic slip areas. The coseismic slips can, therefore, occur not only in mechanical locked zones but also outside the zones accompanied by the rupture of mechanical locking zones.

- Postseismic slip may occur in the regions where the interseismic slip deficits are

induced by mechanical locking, and the seismic moment cannot be completely released by the coseismic slip.

- SMGAs tend to be located at the edges of mechanical locking zones.

Chapter 3

Interplate mechanical locking distributions along the Nankai Trough estimated by the proposed model

3.1. Introduction

In this chapter, the results of applying the proposed model reported in the previous chapter to southwest Japan for estimating mechanical locking distributions along the Nankai Trough are outlined and discussed.

Nankai Trough is the subduction zone where the Philippine Sea Plate subducts beneath the overriding plates such as Amurian and/or Okinawa plate with the convergence rate of 5–6 cm/yr (DeMets et al., 2010). Due to the plate subduction and possible interplate mechanical locking, megathrust earthquakes with $> M$ 8 have repeatedly occurred along the Nankai Trough, and ground shaking and tsunamis following earthquakes have caused significant damages in southwest Japan (Ando, 1975; Garrett et al., 2016). The most recent significant events were the M 7.9 Tonankai Earthquake that occurred in 1944 at Kumano basin and the M 8.0 Nankai Earthquake that occurred in 1946 off Shikoku and extended to the southern Kii peninsula.

Recently, the seafloor GNSS/A observation network has been developed along the Nankai Trough by the Japan Coast Guard and Nagoya University (Tadokoro et al., 2012; Yokota et al., 2018) as well as GEONET; the crustal displacement field including onshore and seafloor can be derived from these observations. The estimation of interplate kinematic coupling distributions using combined onshore and seafloor geodetic observations have been achieved by several studies (Kimura et al., 2019; Nishimura et al., 2018; Watanabe et al., 2018; Yokota et al., 2016). Yokota et al. (2016) first estimated the
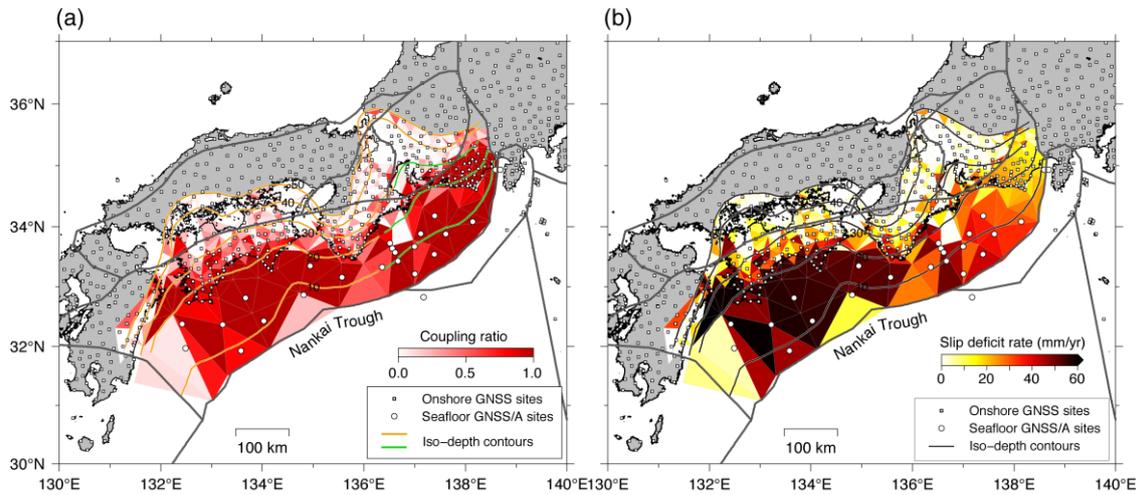

Figure 3.1. Interplate coupling estimated by Kimura et al. (2019). Squares and circles indicate the onshore GNSS and seafloor GNSS/A observation sites, respectively. (a) Map showing the coupling distributions, expressed as coupling coefficient (background color scale). Orange and green lines indicate the iso-depth contours. (b) Map showing the slip deficit rate distribution (background color scale). Black lines on the plate interface indicate the iso-depth contours.

interplate kinematic coupling distributions along the Nankai Trough using the seafloor GNSS/A and coastal GNSS observation data. They revealed the heterogeneity of the coupling distributions both along dip and strike and the strong coupling at the trough axis off Shikoku. Nishimura et al. (2018) and Watanabe et al. (2018) considered the block motion of southwest Japan to distinguish the rigid motion effect from the observed crustal deformation and estimated the kinematic coupling distributions along the Nankai and Sagami Troughs using the onshore GNSS and seafloor GNSS/A observation data. These three previous studies did not optimize the spatial heterogeneity of the uncertainties of kinematic coupling estimates and estimated the coupling coefficient with a smoothing operation. Thus, the kinematic coupling distributions near the trough axis were not reliable. To overcome this problem, Kimura et al. (2019) optimized the spatial heterogeneity of the uncertainties of kinematic coupling estimates by adjusting the

subfault sizes; adjustment was performed by minimizing the objective function that was based on the modified normalized covariance. Then, Kimura et al. (2019) estimated the kinematic coupling distribution along the Nankai Trough considering the block motion on the basis of onshore GNSS and seafloor GNSS/A observational data using the MCMC method (Figure 3.1). As a consequence, the following features were found: along-dip and along-strike heterogeneity of the interplate coupling, as suggested by Yokota et al. (2016); full coupling at the trough axis of off Shikoku and off Tokai regions, implying the possibility of giant tsunami-genesis accompanied by the coseismic slip at the shallowest portion of the plate interface during forthcoming earthquakes, such as the 2011 Tohoku Earthquake; spatial contrast in slip deficit rates between the eastern and western parts along the trough axis was observed due to the difference in convergence rates of incoming plates.

As described above, the interplate kinematic coupling or slip deficit rate distributions along the Nankai Trough have been revealed recently. However, previous studies only derived kinematic conditions on the plate interface, which are the same as in the case of northeast Japan, and the mechanical conditions could not be known from the estimated coupling distributions (Kimura et al., 2019; Nishimura et al., 2018; Watanabe et al., 2018; Yokota et al., 2016). Thus, I applied the proposed model (detailed in Chapter 2.2) to southwest Japan. The results are compared with kinematic coupling distributions estimated by Kimura et al. (2019), coseismic slip distributions, hypocenters, SMGAs of Showa Nankai Trough earthquakes (1944 Tonankai Earthquake and 1946 Nankai Earthquake), slow earthquake distributions, and subducted topographic features along the Nankai Trough.

3.2. Methods and data

3.2.1. Configuration of replica exchange Monte Carlo Sampling

I employed the proposed model and REMC method described in Chapter 2 to southwest Japan. A priori distributions are almost equal to those defined in Chapter 2.2.2. Because the model region depths are from 0 km (corresponding to the depth of trough) to 60 km, z_W is 60 km. The initial conditions of the Euler vectors, internal block strain rate, and coupling coefficients were determined following the method outlined in Chapter 2.2.2. The initial z_{up} and z_{down} are uniquely distributed random values ranging from 0 to 60 km that are consistent with the model region depth range. The number of iterations and number of chains are 2.06×10^6 and 10, respectively. The temperature of the i-th chain was defined as $T_i = 1.67^{i-1}$, so that $T_{10} = 100$. the samples from the first to 10% of the total iteration were rejected as a burn-in. The calculation software and the computer were the same as in Chapter 2.2.2.

3.2.2. Crustal deformation data in southwest Japan

The displacement rates of onshore GNSS and seafloor GNSS/A observation sites in southwest Japan are described in this section. The dataset consist of displacement rates obtained from the F3 daily coordinate data at GEONET observation sites that are provided by GSI (862 sites), displacement rates obtained by campaign observations at ZENISU that is located at Zenisu Reef at southwest and ~50 km far from Kozu Island and conducted by Nagoya and Kochi Universities, previously published displacement rates obtained by campaign GNSS/A observations at seafloor sites conducted by Nagoya

University[1] and Japan Coast Guard (24 sites; Kimura et al., 2019; Yasuda et al., 2017; Yokota et al., 2016). The displacement rates of GEONET sites were obtained by following the data processing procedure described in Chapter 2.2.3, whereas those of the ZENISU site were obtained by linear regression because the campaign observations were conducted once per year; thus, the temporal resolution is too poor to detect annual and semi-annual displacements. In total, 887 sites were used in this evaluation.

The data periods are from August 2006 to December 2009 for GEONET site data, 2005 to 2010 for ZENISU site data, 2004 to 2016 for seafloor GNSS/A site data from Nagoya University (Kimura et al., 2019; Yasuda et al., 2017), and 2006 to 2015 for the seafloor GNSS/A site data of the Japan Coast Guard (Yokota et al., 2016). No major earthquakes occurred during the data period of GEONET sites. Although two intraplate earthquakes of Mj (Japan Meteorological Agency [JMA] magnitude) 7.1 and 7.4 occurred in 2004 near the trough axis southeast of the Kii peninsula, the calculated postseismic displacements of only few millimeters at the nearest seafloor site (Suito, 2017b) did not affect the REMC inversion of mechanical locking distributions, considering the observation accuracy of seafloor GNSS/A observation sites. Thus, coseismic and/or postseismic displacement were not corrected. The offset and postseismic displacement of the 2011 Tohoku Earthquake were already removed by previous studies (Yasuda et al., 2017; Yokota et al., 2016), and the seafloor GNSS/A data are assumed to exhibit a constant interseismic displacement rate.

Mean displacement rate uncertainties were 0.1 (EW), 0.1 (NS), and 0.3 mm/yr (UD) for GEONET sites, 12 (EW), 4 (NS), and 7 mm/yr (UD) for the ZENISU site, 10 (EW) and 10 mm/yr (NS) for the seafloor GNSS/A sites from Nagoya University, and 4 (EW)

---

[1] Seafloor GNSS/A observations performed by Nagoya and Tohoku Universities are shown with green vectors in Figure 3.2

and 4 mm/yr (NS) for the seafloor GNSS/A sites from the Japan Coast guard. Note that this study used three components (EW, NS, and UD) for GEONET and ZENISU sites but two components (EW and NS) for seafloor GNSS/A site data because the UD component of the positioning accuracy of the GNSS/A observations is significantly poor. All displacement rates were translated from the International Reference Frame (ITRF) 2005 to Amurian plate reference frame using the Euler vectors of the MORVEL plate motion model (DeMets et al., 2010; Figure 3.2; Table C.2).
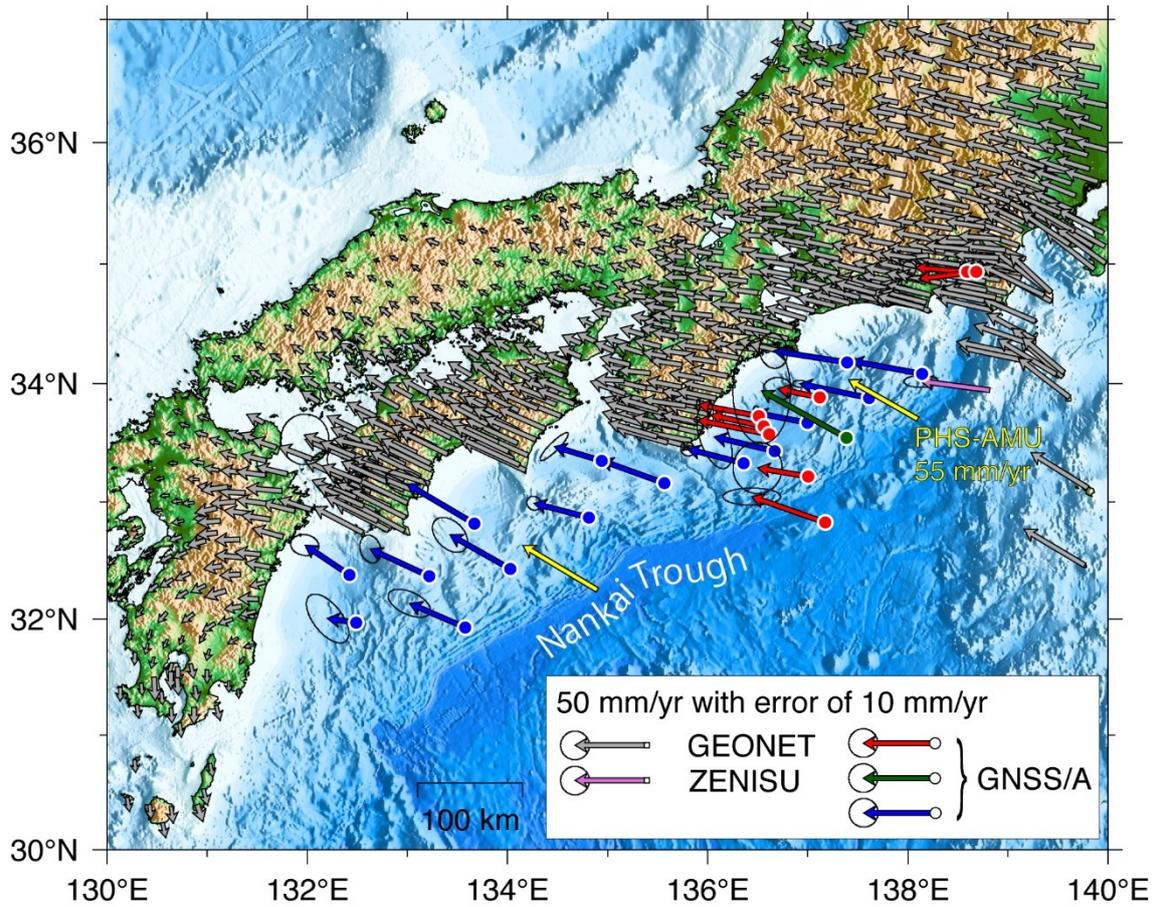

Figure 3.2. Map showing displacement rate vectors used. Gray and purple vectors represent the displacement rate vectors of GEONET and ZENISU. Red, green, and blue vectors represent the displacement rate vectors of seafloor GNSS/A site obtained by Nagoya University, Nagoya and Tohoku Universities (shared site), and the Japan Coast Guard. Yellow vectors show the Philippine Sea (PHS) plate motion relative to the Amurian (AMU) plate calculated on the basis of the MORVEL plate motion model (DeMets et al., 2010). Color scale of the map represents the elevation and bathymetry of SRTM30_PLUS (Becker et al., 2009).

3.2.3. Block boundaries

Southwest Japan spans six plates: the Philippine Sea, Pacific, Okhotsk (North America), Amurian, Okinawa, and Yangtze Plates (Bird, 2003). The Pacific Plate subducts beneath the Philippine Sea and Okhotsk Plates along the Izu–Ogasawara and Japan Trenches, respectively. Philippine Sea Plate subducts beneath the Amurian and Okinawa Plates along the Nankai Trough and Ryukyu (Nansei–Shoto) Trench, respectively. The convergence rate along the Nankai Trough is approximately 5–6 cm/yr based on the MORVEL plate model (DeMets et al., 2010). On the regional scale, the tectonic boundaries of the Amurian Plate are indicated in Figure 3.3. The Median Tectonic Line, extending from western Shikoku to Tokai, is considered to participate in strain partitioning due to the oblique subduction of Philippine Sea Plate along the Nankai Trough (Nishimura et al., 2018; Tabei et al., 2002, 2003). In the western part of the Median Tectonic Line, a right lateral (strike slip) motion of ~5 mm/yr has been estimated from dense onshore GPS observations (Tabei et al., 2002, 2003). The dip angle of the faults has been estimated to be ~30° N. The NKTZ is considered to be a wide shear zone of ~100 km in width based on GPS observations (Sagiya et al., 2000). The North Chugoku Shear Zone (NCSZ), sometimes called the San-in shear zone, is considered to young (Gutscher & Lallemand, 1999; Nishimura & Takada, 2017). Whereas no clear fault zone along the shear zone was found by trenching surveys or geophysical exploration, numerous intraplate earthquakes with a range of seismic magnitudes have been repeatedly observed along the shear zone. The Beppu–Shimabara Graben crosses central Kyushu in the ENE–ESE orientation; it is considered part of the Okinawa Trough, which is a back-arc basin formed by extension within the continental lithosphere that causes the NS extension field in central Kyushu (Tada, 1985). The Zenisu ridge, located at southeast of Nankai Trough with a strike that is roughly parallel to the Nankai Trough axis, was

considered to play an important role in subduction and sliding to the east of the Nankai Trough (Mazzotti et al., 1999, 2001), although the strain condition has not been revealed owing to the lack of available seismic and geodetic observational data.

Based on the global and regional tectonic settings described above, the crust of southwest Japan can be divided into several rigid blocks. In this study, the block division configuration was performed following Kimura et al. (2019) in which the optimum block division configuration were selected on the basis of the Akaike Information Criteria (AIC; Akaike, 1980) value. The optimum block configuration presented by Kimura et al. (2019) contains 12 blocks. In this study, I divided the Okinawa Plate, which is southwest of the Nankai block, into two independent blocks, Okinawa-North and Okinawa-South, to define the horizontal range in which the mechanical locking distributions are estimated. In total, 13 blocks were set in southwest Japan. This revision does not affect the mechanical locking estimations along the Nankai Trough because these two redefined blocks are sufficiently far from the main target region. The block boundaries in southwest Japan used in the present study are shown in Figure 3.4**3.5**.
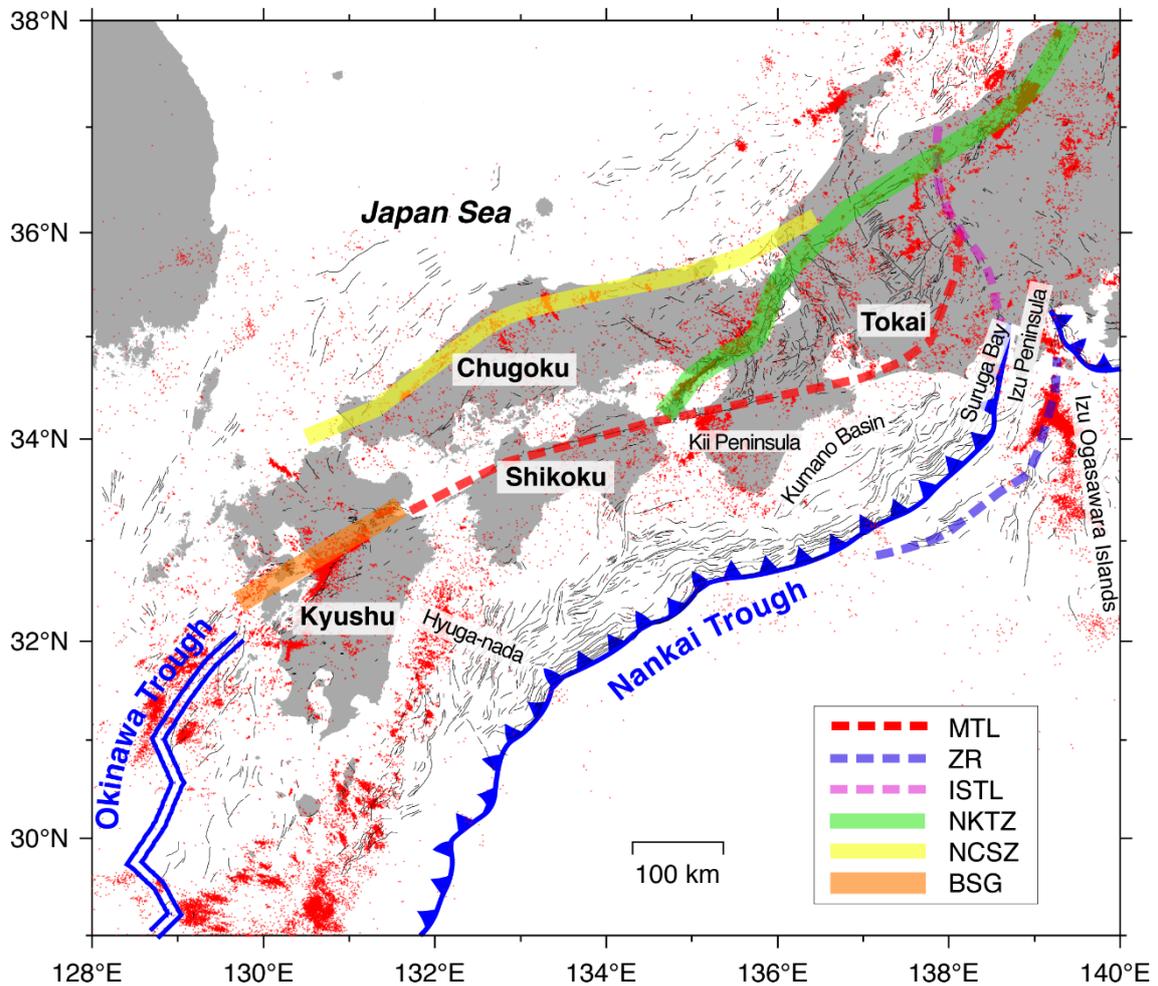

Figure 3.3. Map showing tectonic settings of southwest Japan. Black lines, red dots, and solid or dashed lines show active fault trace lines (Nakata & Imaizumi, 2002), epicenters of ordinary earthquakes, and major tectonic structures (line or zone), respectively. The detected period and magnitude range of plotted earthquakes are 1994–2016 and $Mw \geq 2$, respectively. MTL, Median Tectonic Line; ZR, Zenisu Ridge; ISTL, Itoigawa–Shizuoka Tectonic Line; NKTZ, North Chugoku Shear Zone (San-in shear zone); BSG, Beppu-Shimabara Graben.
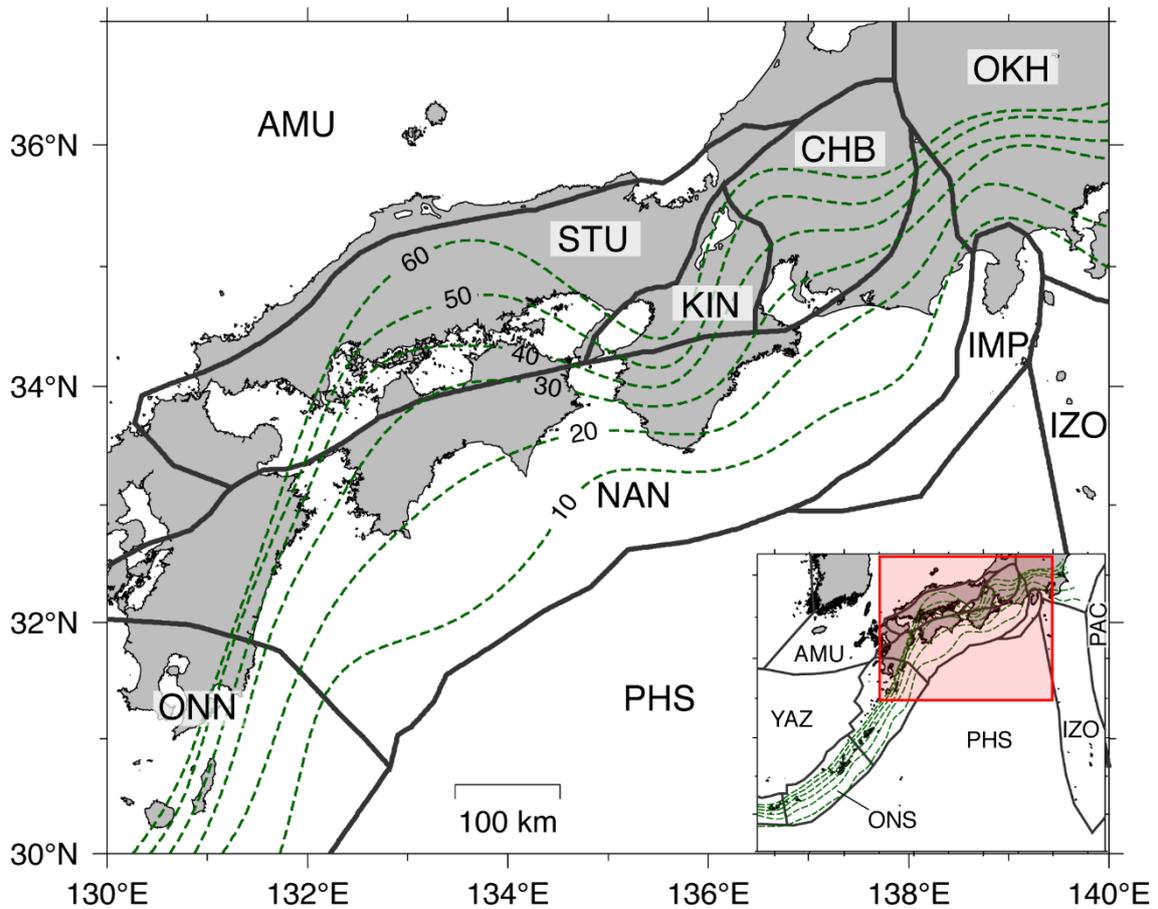

Figure 3.4. Map showing the block boundaries (black bold lines). Abbreviations indicate block names: AMU, Amurian plate; OKH, Okhotsk plate; YAZ, Yangtze plate; ONN, Okinawa-North block; ONS, Okinawa-South block; KIN, Kinki block; CHB, Chubu block; STU, Setouchi block; NAN, Nankai block; IMP, Izu Micro Plate; IZO, Izu Ogasawara block; PHS, Philippine Sea Plate; PAC, Pacific Plate. Green dashed lines indicates the iso-depth contours of subducting plate interfaces (Iwasaki et al., 2015). The small map shown at right-bottom in the map represents the entire model region. The red-hatched region in the small map was focused on in this chapter.

3.2.4. Interface geometries of block boundaries and subducting plates

A combination of subfaults was set on the subducting Philippine Sea Plate interface based on the plate geometry model compiled by Iwasaki et al. (2015). Triangular meshes were adopted for the subfault because triangles can express curved surfaces, such as subducting plate interfaces, more easily than rectangles. The length of the subfault on the plate interface is approximately 20 km in the main target region, 31–36° N and 132–139 ° E. The depth range is from the trough axis to 60 km. It is not necessary to adjust the size because the slip deficit rate on each subfault is not a model parameter; Kimura et al. (2019) adjusted the size of the subfault in the main target region by minimizing the variances of the objective function composed of Green's functions. Although I additionally generated a set of triangular subfaults on the plate interface along the Ryukyu, Sagami, Japan, and Izu–Ogasawara Trenches, their mean lengths are larger (approximately 50–90 km) compared to that of the main target region to decrease the calculation cost because these regions were not the focus of this study. The triangular subfaults are also generated on inland block boundaries. The dip angle of the subfaults is vertical at most block boundaries. Non-vertical subfaults were generated along the following inland block boundaries as an exception: ~30° north-dipping subfaults along the Median Tectonic Line (the block boundary between Nankai and Setouchi blocks) referred to Tabei et al. (2002, 2003); ~70° west-dipping subfaults along the West Sagami Bay Fracture (block boundary between Izu Micro Plate and Izu–Ogasawara block) referred to Koyama (1995); and ~25° north-dipping subfaults along the Zenisu ridge (block boundary between Philippine Sea and Izu Micro Plates) referred toLallemant et al. (1989). The mechanical locking distributions are estimated along the northern most part of Ryukyu Trench (plate interface between Philippine Sea Plate and North-Okinawa block), colliding zone of Izu peninsula (block boundary between Izu Micro and Okhotsk

plates), and Sagami Trough (plate interface between Izu–Ogasawara block and Okhotsk Plate), as well as along the Nankai Trough to avoid abrupt changes in boundary conditions at the eastern and western edges of the Nankai Trough. The coupling coefficients are estimated along the other subduction zones and block boundaries. The three-dimensional mapping of subfaults on the plate interface and block boundaries are shown in Figure 3.5(a). The z_{up} and z_{down} along the Nankai Trough were sampled along the pink lines shown in Figure 3.5(b).
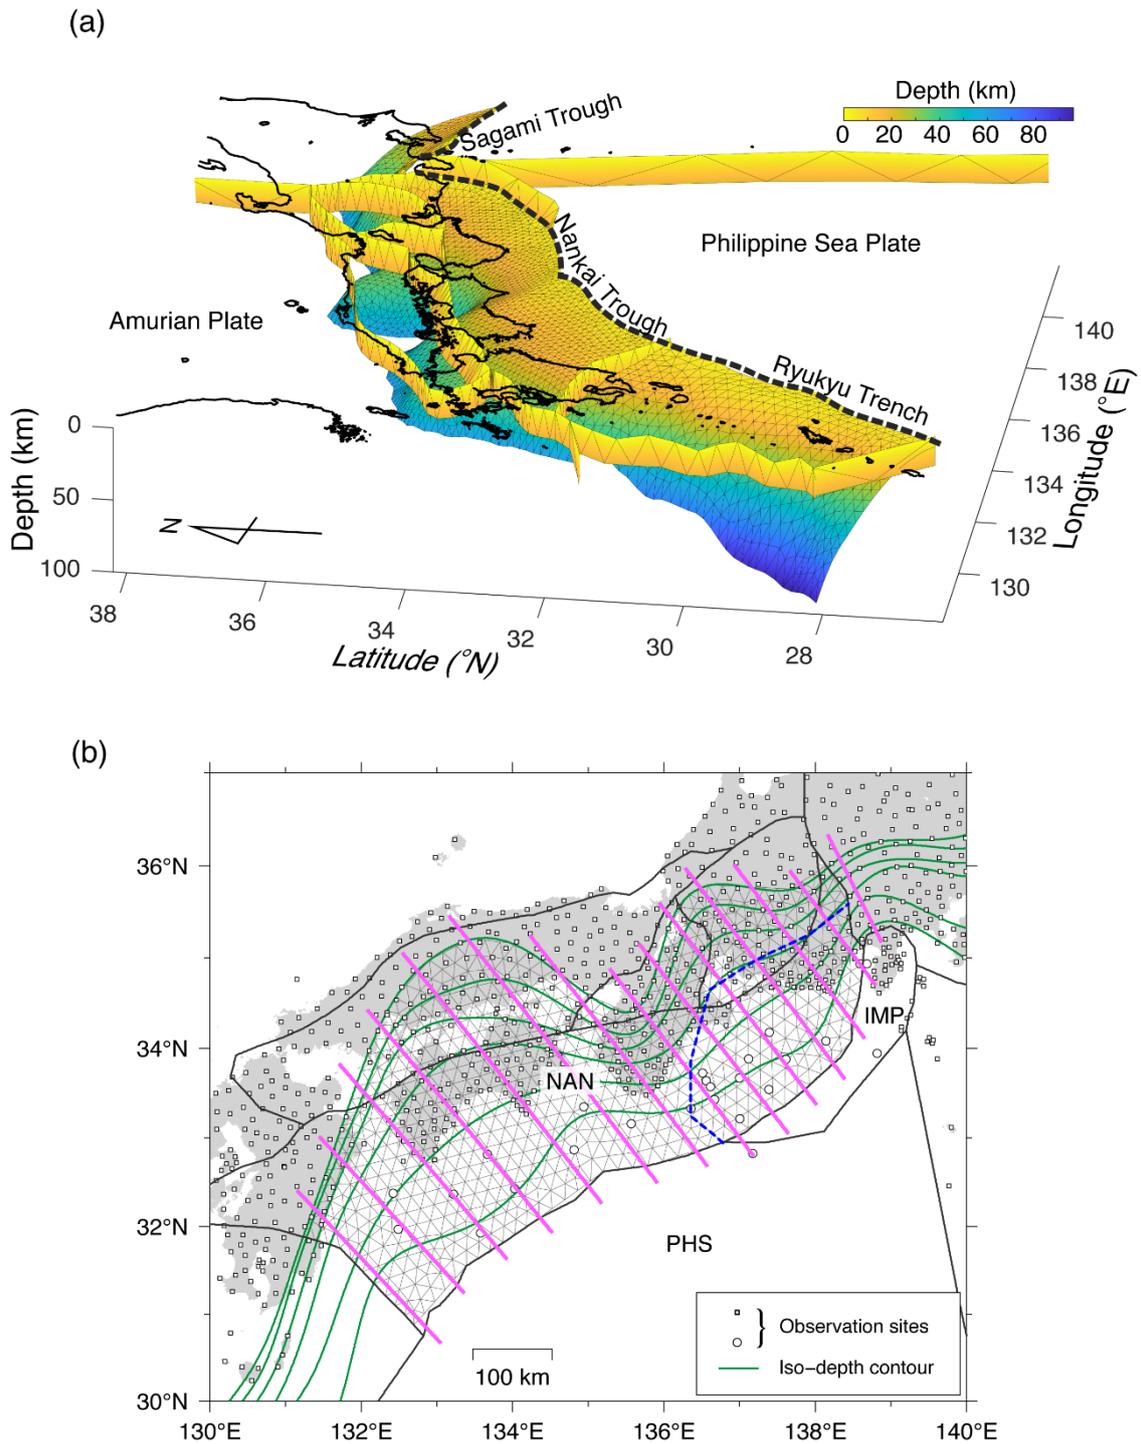

Figure 3.5. Interface geometries of block boundaries and subducting plates. (a) The three-dimensional map showing the interfaces of blocks and subducting plates. This map shows the WSW orientation. Triangular meshes on the interface are subfaults. The geometry of the subducting plate interface was taken from Iwasaki et al. (2015). The color scale

indicates the interface depths. Black solid and dashed lines represent coast lines and trough axes. (b) Map showing subfaults (gray triangles) on the plate interface along the Nankai Trough. Green lines indicate iso-depth contours of the upper surfaces of the subducting plate interfaces, with a depth interval of 10 km starting from 10 km in depth. Blue dashed line indicates the boundary of the plate interface. The lower surface of the overriding Nankai block is contacting with the upper surface of the subducting Philippine Sea Plate at the west and north of the line, whereas it is contacting with the upper surface of the subducting Izu Micro Plate at the east and south of the line.

3.3. Estimated mechanical locking distributions and slip deficit rates

The results mainly focused on the mechanical locking distributions estimated on the plate interface along the Nankai Trough. The results of the rigid block motion (Euler vectors) and block internal strain rates are summarized in the appendix section. Figure 3.6 shows the estimated mechanical locking distributions along the Nankai Trough. The color scale indicates the locking probability derived from Equation (29). Figure 3.7 shows the typical examples of PDFs of the up-and down-dip depth limits and the locking probability calculated from Equation (29) along the lines of A, B, C, D, E, and F shown in Figure 3.6. It was found that the estimated mechanical locking distributions can be divided into four segments. Hereinafter, the mechanical locking segments are called the Hyuganada, off Shikoku, off Kii, and off Tokai segments from the west to east. The plate interface of the off Shikoku, off Kii, and off Tokai segments were estimated to be mechanically locked at the trench depths, whereas the up-dip limit is ~10 km in depth at the Hyuganada segment. The down-dip limit is heterogeneous among the four locking segments: 60 km in Hyuganada, ~20 km off Shikoku, ~10 km off Kii, and 10–25 km off Tokai.

Some subfaults exhibit low P_l around the subfault with higher P_l (>0.8). The

spreading of the subfaults exhibiting low P_l around those with high P_l is assumed to be a spatial distribution of estimation uncertainties of mechanical locking depths. I quantified the uncertainties by 95 percentile confidence intervals obtained from posterior PDFs (Figure 3.7). PDFs of the down-dip depths of locking zones exhibited single peaks along five lines excluding line A in the Hyuganada segment. PDFs of the up-dip depths are shallower than the trough depths along five lines excluding line A. The 95 percentile confidence intervals of the up- and down-dip depths of the mechanical locking zone along the six lines were 27 (up-dip in A), 32 (down-dip in A), 88 (up-dip in B), 4 (down-dip in B), 32 (up-dip in C), 2 (down-dip in C), 67 (up-dip in D), 12 (down-dip in D), 90 (up-dip in E), 20 (down-dip in E), 99 (up-dip in F), and 12 km (down-dip in F). Large 95 percentile confidence intervals can be seen in up-dip limitation depths at lines B, C, D, E, and F. Moreover, the PDFs of up-dip limitation depths exhibit a flatter shape at depth ranges shallower than trench depths at these lines. The posterior PDFs at the depth ranges outside the model region depths (i.e., shallower than the trench or deeper than the bottom, ~60 km in this study) should be mathematically similar to the prior PDFs at depth ranges outside the model regions depths because the likelihood would not change when the up- or down-dip limitation depths are sampled only at depths outside the model region depths (Equation 17). That is, each depth value, which was sampled as the posterior PDF at depth ranges outside the model region depths, indicates the random value following the prior PDF and has no physical meaning. Therefore, the flattened shape PDF shape of the up-dip limitation depths at lines B, C, D, E, and F imply the sampling from the prior PDF. Moreover, large 95 percentile confidence intervals, which are exhibited in up-dip limitation depths at lines B, C, D, E, and F do not indicate the significant estimation uncertainties of up-dip limitation depths. Note that almost all posterior PDFs were obtained at depth ranges shallower than the trench at lines B, C, D, E, and F, which may

suggest mechanical locking with extremely high probability at the trench, although each depth value itself has no physical meaning. Almost all down-dip limitation depths were sampled inside the model region depths along the six lines. The 95 percentile confidence intervals of down-dip limitation depths vary within ~30 km among the six lines, indicating that the spatial heterogeneity of the 95 percentile confidence intervals of down-dip limitation depths is smaller than that in northeast Japan (Chapter 2.3). This implies that the resolution at the offshore region along the Nankai Trough is more homogeneous than that in northeast Japan. The down-dip limitation depths would be constrained by seafloor GNSS/A observation data as well as by onshore GNSS observation data. The spatial homogeneity of the onshore GNSS observation network in southwest Japan is similar to that in northeast Japan. Conversely, the spatial homogeneity of the seafloor GNSS/A observation network in southwest Japan is much higher than that in northeast Japan. The seafloor GNSS/A sites (24 sites in total) were installed from Suruga Bay to Hyuganada with average spatial intervals of 50–80 km in southwest Japan. However, there were only 8 seafloor GNSS/A observation sites from central to southern Tohoku with average spatial intervals of 60–100 km in northern Japan. No sites are installed from northern Tohoku to Hokkaido. Thus, the resolution could be homogeneously enhanced at the offshore region in southwest Japan, whereas the resolution could be enhanced only at the region where the seafloor GNSS/A network exists (i.e., central to southern Tohoku) in northeast Japan.

The slip deficit rate distributions were calculated (Figure 3.8) from Equation （10） on the basis of the mechanical locking distribution and estimated Euler vectors (Table B.1). In the calculation, I selected the subfault with a locking probability P_l larger than 0.5 as the mechanically locked subfaults. The slip deficit rate contrast can be seen between eastern and western part in the model region (~19 mm/yr in the eastern part and ~52

mm/yr in the western part), because the two individual blocks, with the Philippine Sea Plate in the western part and Izu Micro Plate in the eastern part, subduct beneath the overriding Nankai Forearc block with different convergence rates.

The slip deficit rates on the mechanical locking zone are equivalent to the plate convergence rates (relative block motion rates). Thus, the uncertainties of the slip deficit rate directly reflected by uncertainties of the relative block motion (Euler vectors). To quantitatively confirm these uncertainties, I first plotted the two-dimensional PDF of the Euler vectors of subducting Philippine Sea and Izu Micro Plates relative to the Nankai Forearc block (Figure 3.9). The differences in pole locations of the above two plates relative to the Nankai Forearc block are approximately ~10° in longitude and ~8° in latitude. Both Euler poles were estimated with uncertainties larger in longitude than in latitude. The mean angular velocities of the Euler vectors of the Philippine Sea Plate are approximately four times higher than those of the Izu Micro Plate. The uncertainty of the angular velocity of the Philippine Sea Plate is twice as large as that of the Izu Micro Plate. Figure 3.10 shows the two-dimensional PDF of the relative block motions on the mechanical locking segments in eastern and western parts of the model region. Unimodal Gaussian distribution with uncertainties of 4–5 mm/yr can be seen in PDFs of northern and eastern plate convergence rates both in eastern and western areas (Figure 3.10a, c, d, and f). Moreover, the two-dimensional PDFs exhibit concentric distributions (Figure 3.10b and e). Hence, the uncertainties are almost equal in all orientations, and there is no directivity in plate convergence rate uncertainties.
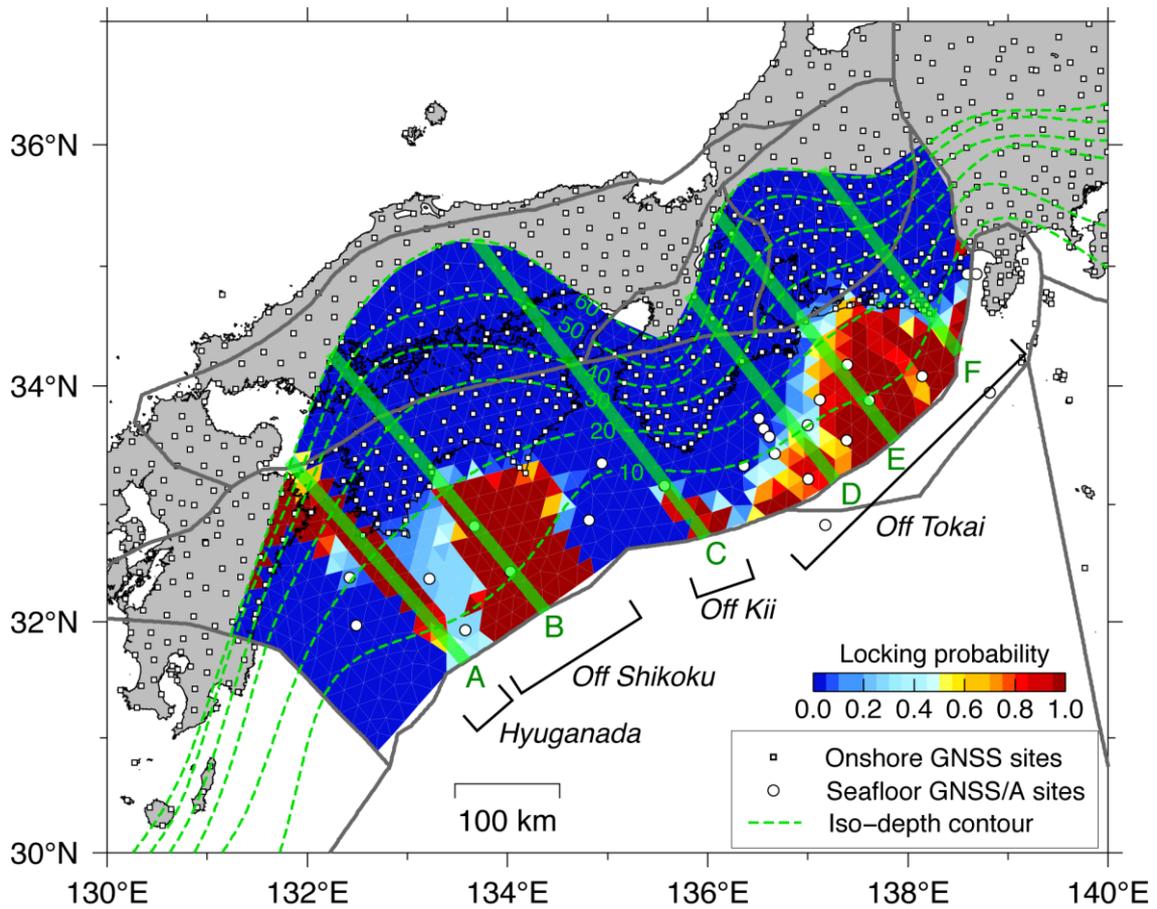

Figure 3.6. Map showing estimated mechanical locking distributions on the plate interface along the Nankai Trough. Background color scale indicates the locking probability of each subfault given by Equation (29). Green dashed lines indicate the iso-depth contours of the subducting plate interface. Names of mechanical locking segment are italicized.
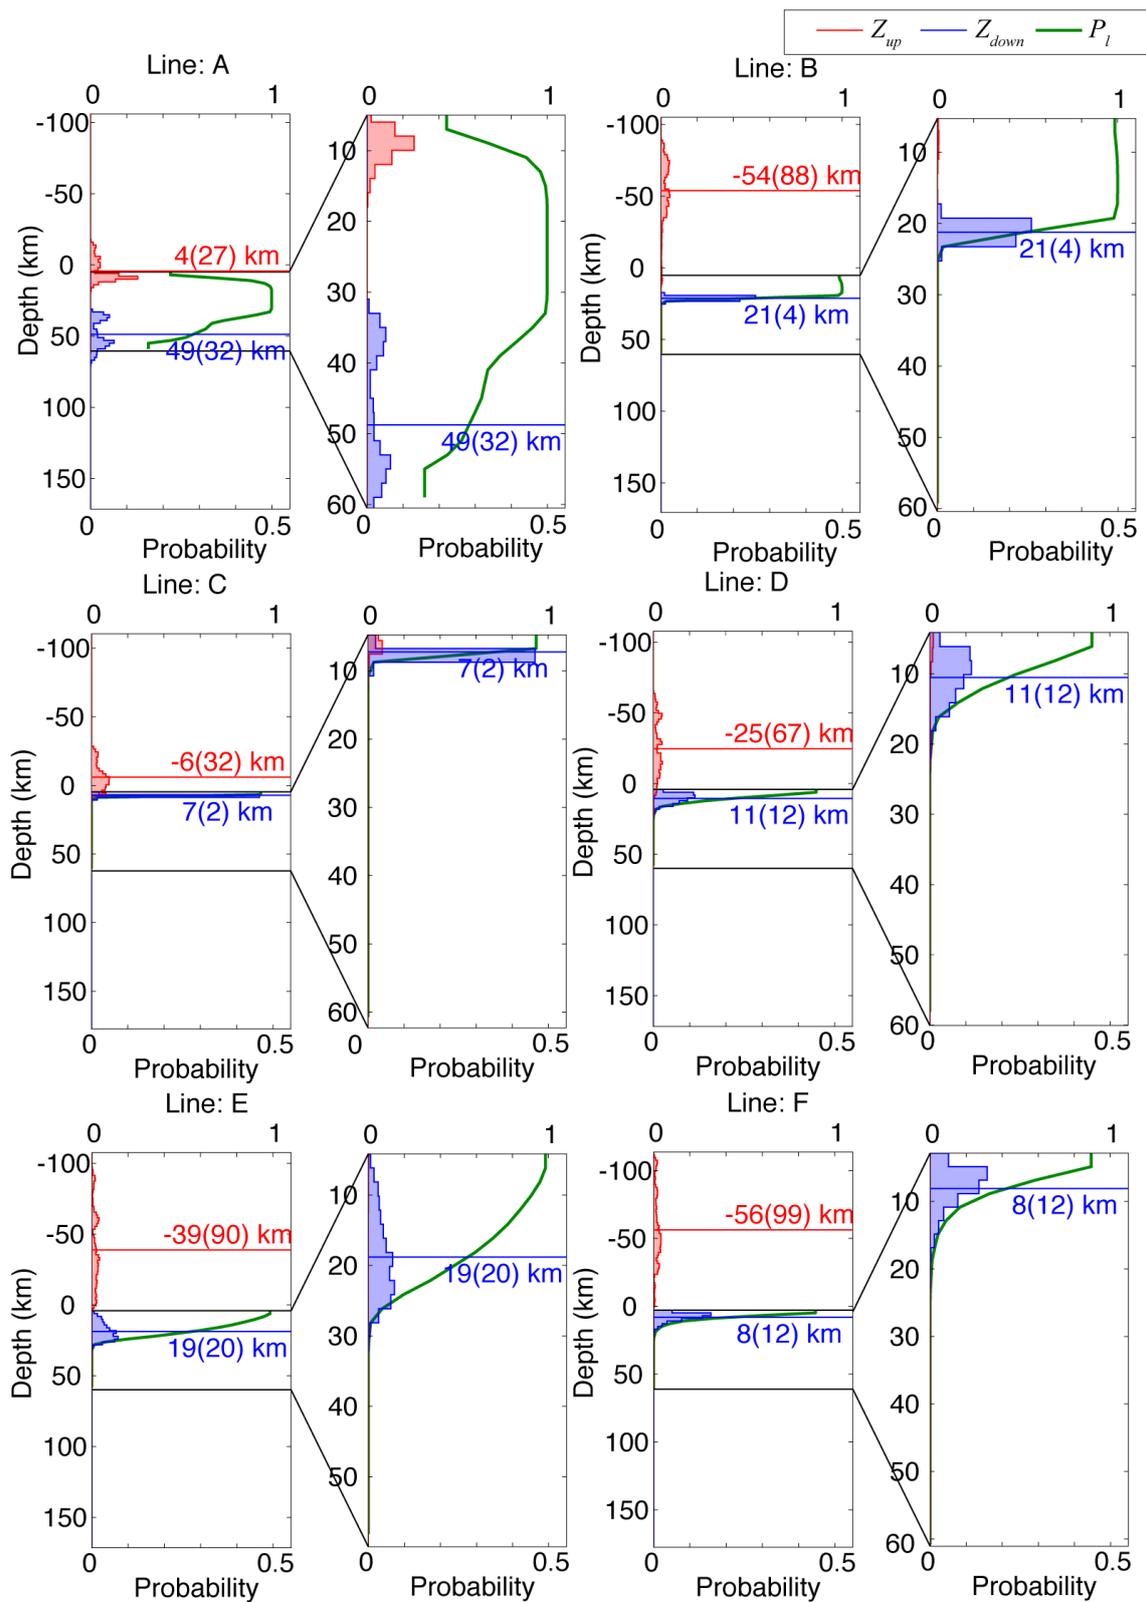

Figure 3.7. Graphs showing PDFs of the up- and down-dip depths and P_l along the line

A, B, C, D, E, and F shown with green solid lines in Figure 3.6. For each subfigure, PDFs and P_l are plotted for whole sampling depths in the left panels and for model area depths (i.e., top and bottom depths coincide with the trench and 60 km depth, respectively) in the right panels. PDFs are normalized such that the sum of the value for each bin becomes 1. Horizontal red and blue solid lines indicate the mean value of the up- and down-dip depths calculated from all the samples. Mean values are described on or under the lines. The 95 percentile confidence interval values are described in brackets to the right of the mean value. The scales of PDFs and P_l are shown in the bottom and top axes for each panel, respectively.

(a) Map showing the selected subfaults (black subfault) whose locking probabilities is larger than 0.5 and that were assumed to be mechanically locked. (b) Map showing the slip deficit rate distributions calculated on the basis of the mechanical locking distributions and Equation (10). The two-dimensional PDFs of relative motion (slip deficit) rates at cross A and B are shown in Figure 3.10.
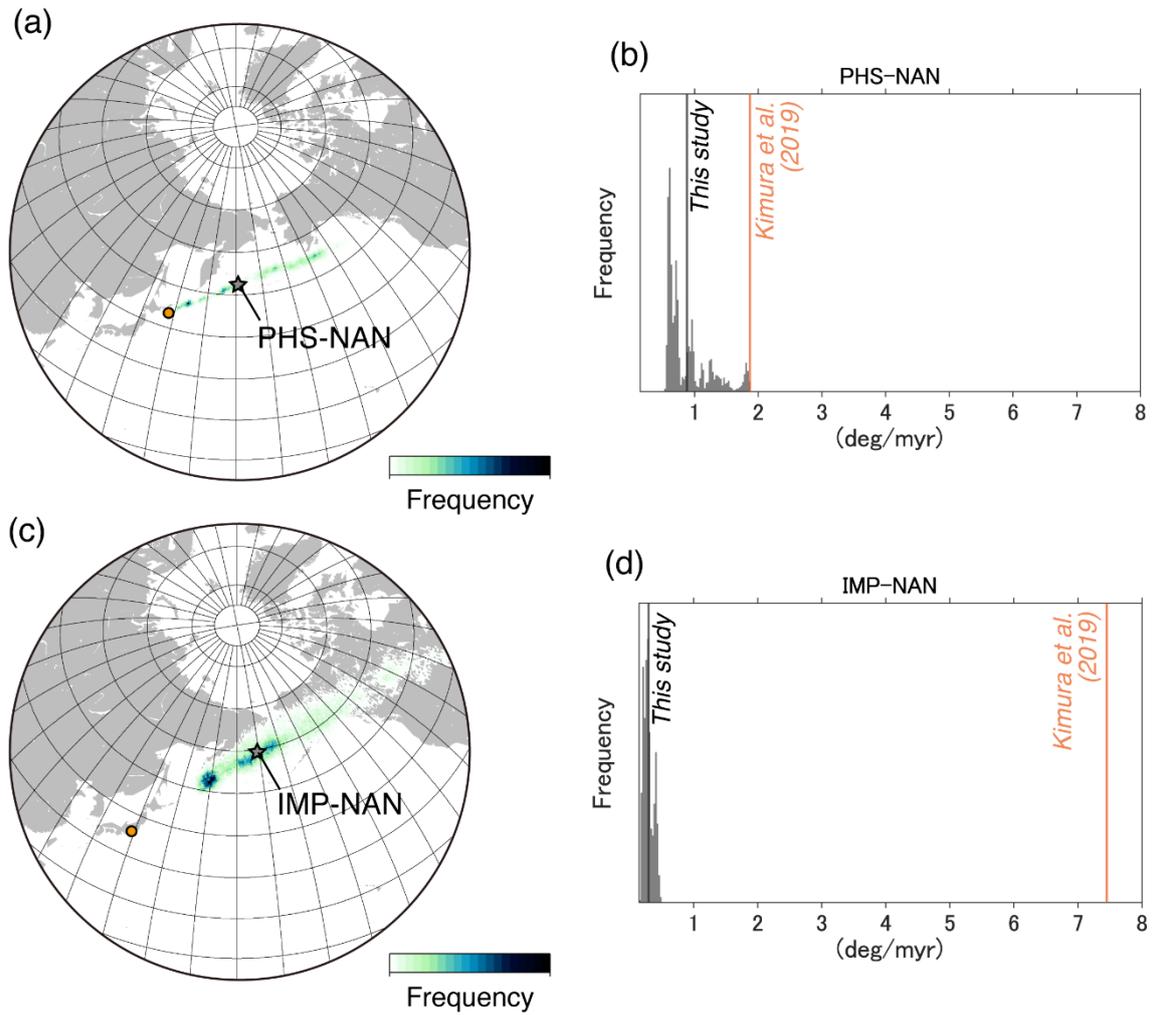

Figure 3.9. Uncertainties of Euler vectors of subducting plates relative to the Nankai Forearc block. (a) Map showing the two-dimensional PDF of the Euler vector of the subducting Philippine Sea Plate relative to Nankai Forearc block. The background color scale means the probability distribution of the Euler pole location. The gray star indicates the mean value, and the orange circle indicate the Euler pole estimated by Kimura et al. (2019). (b) Graph showing the probability distribution of the Euler pole angular velocity of the subducting Philippine Sea Plate relative to the Nankai Forearc block. The clockwise rotation corresponds to positive angular velocity. The black vertical line indicates the mean value. The orange vertical line indicates the angular velocity estimated by Kimura et al. (2019). (c) Same as (a) but the Euler vector of the subducting Izu Micro Plate relative to the Nankai Forearc block. (d) Same as (b) but the Euler vector angular velocity of the subducting Izu Micro Plate relative to the Nankai Forearc block.
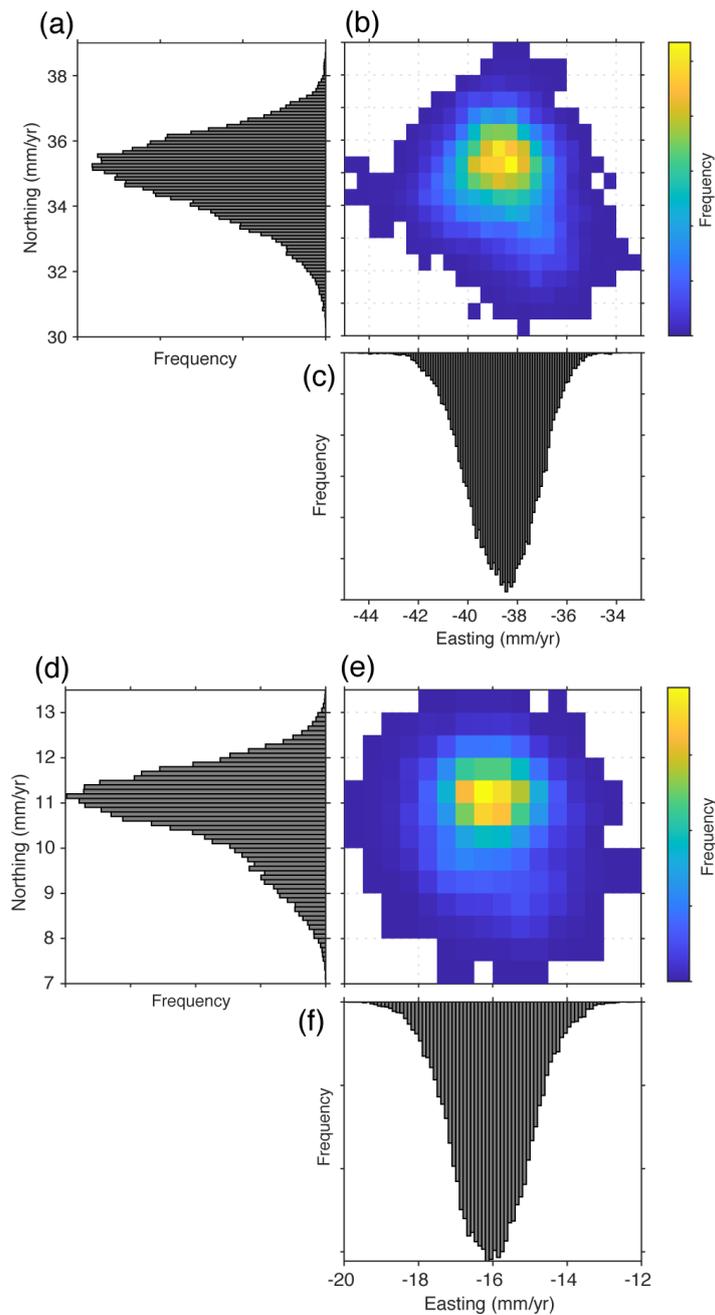

Figure 3.10. Uncertainties of relative motion rate in the western (point A in Figure 3.8b) and eastern (point B in Figure 3.8b) parts of the model region. (a), (c) Graphs showing the PDF of the northern and eastern plate convergence rates at the western part of the model region, respectively. (b) Graph showing the two-dimensional probability distribution of the northing and easting plate convergence rates at the western part of the model region. Background color indicates the normalized probability density. (d), (f) Same as (a) and (c) but for the eastern part of the model region, respectively. (e) Same as (b) but for the eastern part of the model region.

3.4. Discussion

3.4.1. Comparison with kinematic coupling distributions

In this chapter, I reveal the spatial relationship between mechanically locked and kinematic coupled regions. Although the kinematic coupling distributions along the Nankai Trough were estimated in many previous studies, the results vary owing to several factors such as the dataset, model configuration, and inversion approach. Ideally, the differences in each factor should be reduced to compare the spatial distributions of mechanical locking and kinematic coupling. Thus, I compared the result of this study with the kinematic coupling distribution estimated by Kimura et al. (2019) in which the dataset and block division configuration were the same as that in this study. While the plate interface geometry of this study is different than that used in Kimura et al. (2019), I did not discuss it in depth because the mechanical locking distribution would not change significantly owing to the slight variation in plate interface geometry, as discussed in Chapter 2.4.4.

Figure 3.11(a and b) shows the mechanical locking distributions estimated in this study and the kinematic coupling distribution (Kimura et al., 2019), respectively. Briefly, mechanically locked zones with high locking probability exhibit high coupling, such as Shikoku and Tokai. However, there are some regions that exhibit low locking probability but high kinematic coupling: offshore region between the Hyuganada and off Shikoku locking segments, offshore regions between the off Shikoku and off Kii locking segments, and the region north of the off Tokai locking segment. The regions exhibiting high locking probability in this study coincide with those exhibiting high-coupling in the study by Kimura et al. (2019), but the reverse is not always true. I selected the subfaults exhibiting locking probability larger than 0.5 as the mechanically locked zones (hatched regions in

Figure 3.11a). Figure 3.11(c) shows the slip deficit rate distributions calculated on the basis of mechanical locking distributions. Moreover, Figure 3.11(d) shows the slip deficit rate distributions estimated by Kimura et al. (2019). There are clear slip deficit rate contrasts between western and eastern parts of the model region in both slip deficit rate distributions because the two individual blocks, Philippine Sea Plate in western part and Izu Micro Plate in eastern parts subduct beneath the overriding Nankai Forearc block with different convergence rates. The slip deficit rate in this study is lower than that in Kimura et al. (2019) because the Euler vector estimates, which prescribe plate convergence rates, differ between this study and Kimura et al. (2019), as shown in Figure 3.9. High slip deficit rates can be observed at the mechanical locking regions in this study and at the regions exhibiting high kinematic coupling (Figure 3.11c and d). Additionally, some regions exhibit high slip deficit rates but low or almost zero locking probability, particularly at offshore regions between Hyuganada and Shikoku locking segments and the region north of the Tokai locking segment. As a consequence, the slip deficit rates at these regions are similar to slip deficit rates at the same regions in Kimura et al. (2019). The slip deficit rate is ~29 mm/yr and the locking probability is almost zero at the offshore region between the off Shikoku and off Kii locking segments. This value is ~60% of the slip deficit rate in the mechanical locking zone at off Shikoku segment and ~50% of the slip deficit rate estimated at the same region in Kimura et al. (2019). The residuals are similar between this study and Kimura et al. (2019) in this region excluding the coastal area of southeastern Shikoku, as shown in Figure 3.11(e and f). This indicates that the surface crustal deformation can be explained although the slip deficit rate is ~50% of that estimated by Kimura et al. (2019) at the offshore region between the off Shikoku and off Kii locking segments. If the mechanical locking is situated at this region (Figure 3.12b), residuals become larger at the seafloor GNSS/A sites and onshore GEONET sites in the

western Shikoku and southern Kii peninsula (region enclosed by the red line in Figure 3.12d). This suggests that crustal deformation in and around this region can be explained by slip deficits induced by mechanical locking in Shikoku and off Kii segments, even if the plate interface at the offshore region between the Shikoku and Kii locking segments is creeping (i.e., mechanically unlocked). It was revealed that the region between the off Shikoku and Kii locking segments is likely creeping.

Again, the plate interface exhibiting kinematic high coupling is not always mechanically locked. The high coupling (high slip deficit rate) on the plate interface that is not mechanically locked can be explained by the slip deficit induced by the mechanical locking at the adjacent regions. In the region that is not mechanically locked but where mechanical locking zones exist at the adjacent regions, it is difficult to distinguish the mechanically locked zone from the slip deficit rate distributions estimated on the basis of the pure kinematic framework, because the large slip deficit (whose velocity is lower than the slip deficit rate on the mechanical locking zone but much higher than zero) can be induced by the mechanical locking of the adjacent regions as shown in Figure 3.11(c) or suggested by Herman et al., (2018). Thus, it is useful to adopt the new physical model developed in this study to estimate the mechanical locking zone from geodetic observation data.
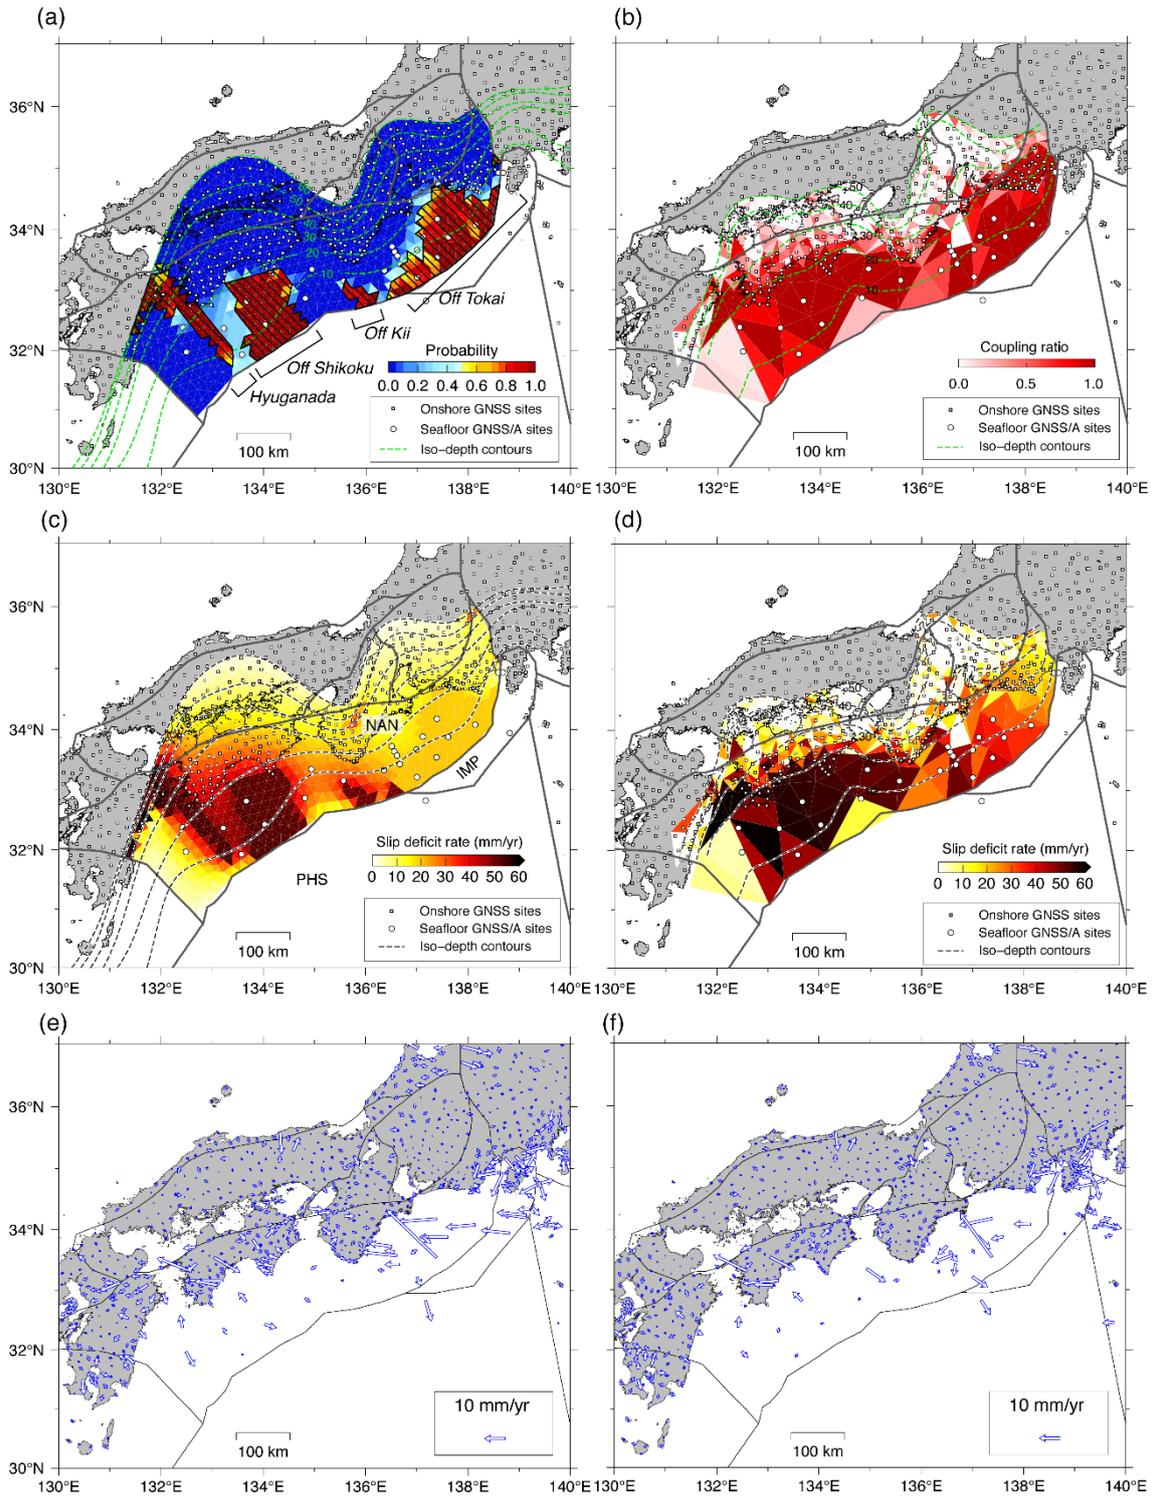

Figure 3.11. Comparison of mechanical locking distributions, kinematic coupling distributions, slip deficit rate distributions, and residuals. (a) Map showing the mechanical locking distributions along the Nankai Trough expressed as the locking probability. The hatched regions exhibit the locking probability larger than 0.5. (b) Map showing the

kinematic coupling distributions estimated by Kimura et al. (2019). The color scale means the coupling coefficient at each subfault. (c) Map showing slip deficit rate distributions on the plate interface calculated on the basis of the mechanical locking zones, hatched regions in (a). Abbreviations indicate the block name (Figure 3.4). (d) Map showing the slip deficit rate distribution on the basis of the kinematic coupling distribution (Kimura et al., 2019). (e) Map showing the residuals, observed displacement rate minus calculated displacement rate obtained in this study. (f) Same as (e) but for Kimura et al. (2019).
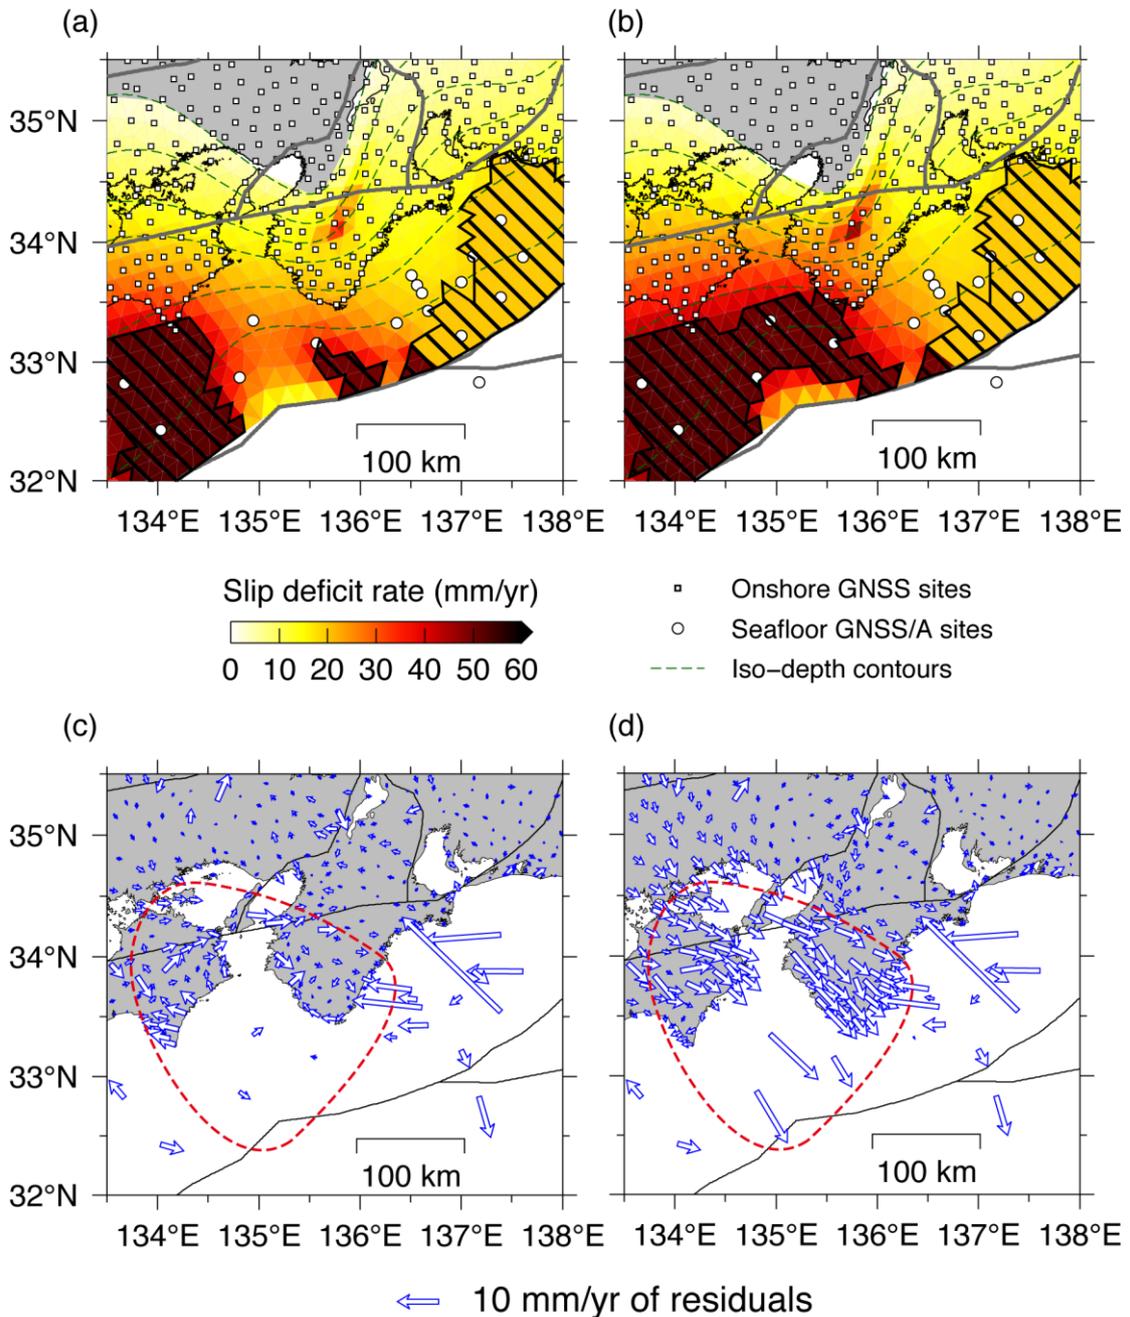

Figure 3.12. Comparison of the slip deficit rate distributions and residuals. (a) Map showing the slip deficit rate distributions at the offshore region between the Shikoku and Kii locking segments. Hatched zones represent the mechanical locking zones that are the same as those in Figure 3.11(a). (b) Same as (a) but the artificial mechanical locking zone was situated at the region exhibiting almost zero locking probability at the offshore region between the off Shikoku and off Kii locking segments. (c), (d) Residuals which were calculated on the basis of the slip deficit rate distributions shown in (a) and (b), respectively.

3.4.2. Implicated frictional states from slow earthquake distributions

Southwest Japan is a well-studied area for understanding various types of slow earthquakes (Obara, 2011) that contains low frequency tremors (LFTs, or low frequency earthquakes; LFEs), very low frequency earthquakes (VLFEs), and long (short) term slow slip events (SSEs). The signal of LFT (or LFE) and VLFE are detected by high-sensitivity or broad-band seismometers. The LFTs are weak seismic motion with a long duration time and without distinct P or S phases (Obara, 2011). The seismic wave of LFT has a predominant frequency ranging 1–10 Hz. The LFE is a pulsive-like seismic wave that sometimes occurs with LFT. The source location LFT (or LFE) is detected using a particular method, such as the envelope correlation method (Obara, 2002) because it is difficult to identify P or S wave arrivals. The VLFEs radiate weak seismic waves with a predominant frequency of 0.01–0.05 Hz that are sometimes accompanied by LFT bursts (Obara, 2011). The source location of VLFEs is difficult to determine using standard earthquake detection methods, as well as the LFT or LFE, and thus, GRiD moment tensor method (e.g., Ito et al., 2007) that is a kind of grid-search approach is used. These earthquakes have been detected at both the shallow portion (from the trench to ~10 km in depth) and the deep portion (30–45 km in depth) of the plate interface along the Nankai Trough (Obara, 2011; Obara & Ito, 2005). VLFEs at shallow portions have been detected on the splay fault in accretionary prisms (Toh et al., 2018). The SSE is detected by geodetic observational instruments such as GNSS, strain meter, and tilt meter, not detected by the seismometers because the SSE itself does not radiate seismic waves but causes crustal deformation. The duration of the SSE spans approximately few days to few months ("short-term SSE") or few years ("long-term SSE"). SSEs have been detected mainly at   depths of 30–45 km (Nishimura et al., 2013). Recently, the occurrence of shallow SSEs (~10 km in depth) have also been reported following the development of

seafloor geodetic observational instruments (Araki et al., 2017; Yokota & Ishikawa, 2020).

Figure 3.13 shows the spatial distributions of slow earthquakes detected in southwest Japan as well as the mechanical locking distributions estimated in this study. The locations of deep tremors are almost the same as those of deep VLFE. Deep SSE seems to occur not only at the depth corresponding with the deep tremor and/or VLFE occurrence zone but also at depths slightly shallower than that of tremor or VLFE, particularly in the western Shikoku and in the Tokai region. The down-dip limitation depths of the estimated mechanical locking zones are almost complementary to the occurrence zones of deep slow earthquakes. Most shallow slow earthquakes were detected at depths shallower than ~10 km. Although the deep slip earthquakes were detected continuously along the strike of the plate boundary, shallow slow earthquakes were detected with a clear gap along the trough. Comparing the mechanical locking distribution with the shallow slow earthquake occurrence zones, it was found that most shallow slow earthquakes were detected in regions exhibiting zero or low locking probabilities. The number of events detected inside the mechanical locking zone is much lower than that detected at the region exhibiting zero or low locking probabilities. The shallow slow earthquakes seem to be detected on the plate interface where the locking probability is high off southeastern Kii peninsula. However, Toh et al. (2018) analyzed the occurrence depths of shallow events detected at the segment of off southeastern Kii peninsula and suggested that the detected events in the northeastern part of the segment might occur on the splay fault in the accretionary prism, whereas that of the southeastern part of the segment might occur on the plate interface. As a consequence, regions of most shallow earthquakes off southeastern Kii peninsula do not coincide with the regions exhibiting high locking probabilities. Thus, the complementarity of spatial distributions between mechanical locking zones and the slow earthquake occurrence zones can be

observed both in shallowest part and deeper part of the plate interface. Although Kimura et al. (2019) pointed out the complementarity between the high-coupling and the deep tremor distributions, they could not discuss with respect to mechanical locking or frictional states on the plate interface based on kinematic coupling distributions.

Slip behaviors on the plate interface may be controlled by frictional states on the plate interface. The slow earthquakes are considered to exhibit a very slow slip phenomena compared to ordinary interplate earthquakes (Obara, 2009). The frictional states on the plate interface where the ordinary interplate earthquakes and the slow earthquakes are suggested to be unstable sliding (Brace & Byerlee, 1966; Dieterich, 1979) and conditionally stable (or stable) sliding (Obara, 2020; Obara & Kato, 2016). The slow earthquake and the estimated mechanical locking distributions exhibit obvious spatial complementation, implying that the estimated mechanically locked zones represent a frictionally unstable sliding interface. This implication is very important because the estimated mechanical locking distributions may correctly reflect the frictional states on the plate interface, although the new physical model used to estimate the mechanical locking distributions did not model any physical parameters exactly prescribing the frictional states on the plate interface, such as the rate- and state-dependent friction law (Dieterich, 1979). The results of the comparison of mechanical locking distributions with slow earthquake distributions indicate that the proposed model can be applied to estimate frictional properties on the plate interface. Understanding frictional property leads to the prediction of slip behaviors on the plate interface during earthquakes and thus may contribute to improved earthquake disaster mitigation.
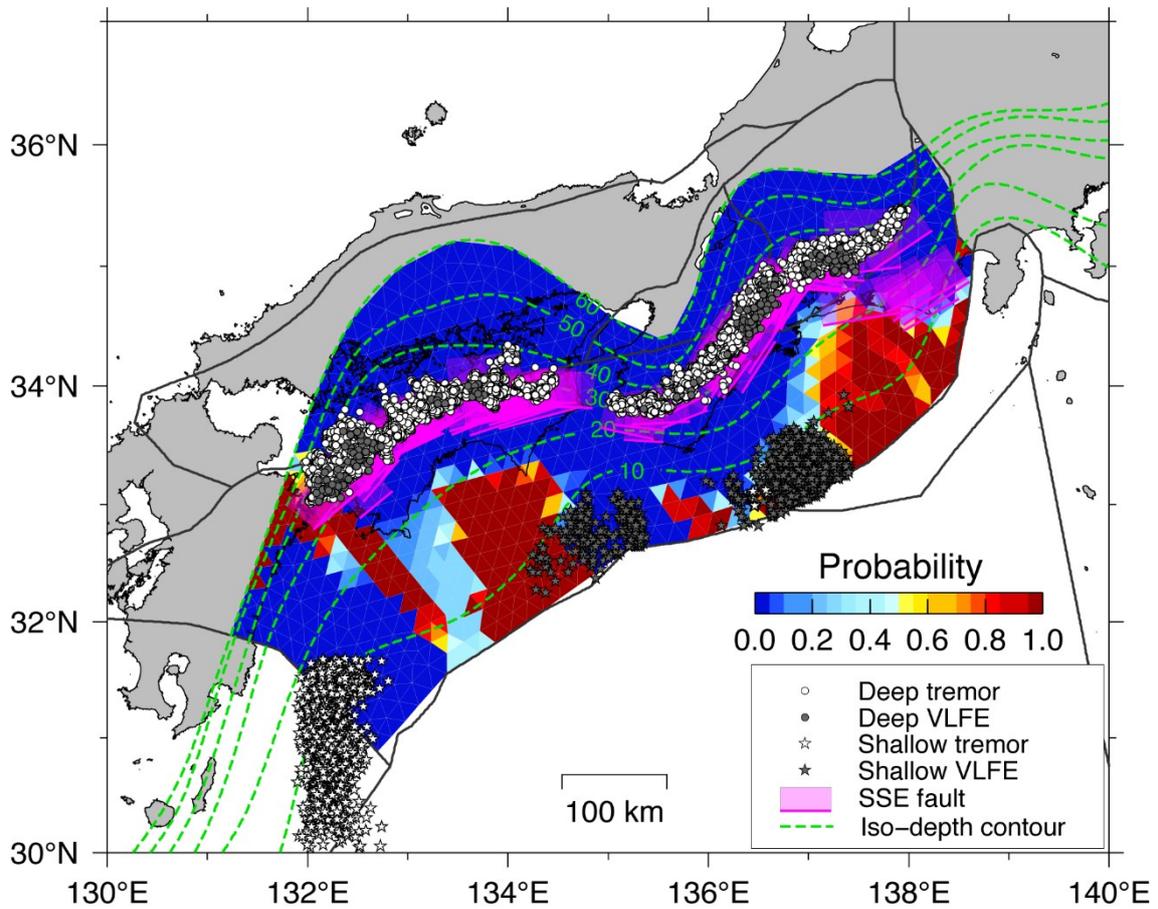

Figure 3.13. Comparison of mechanical locking distributions with slow earthquake distributions in southwest Japan. The background color indicates the locking probability. Deep tremor, deep VLFE, shallow tremor, and shallow VLFE were shown as white circles, gray circles, white stars, and gray stars, respectively. Deep SSE is shown with magenta rectangles. The following are references for each slow earthquake: Deep tremor, Obara et al. (2010); Deep VLFE, Ito et al. (2009); Deep SSE, Nishimura et al. (2013); Shallow tremor, Obana & Kodaira (2009) and Yamashita et al. (2015); Shallow VLFE, Takemura et al. (2019). Detection periods are from 2001 to 2017 for deep tremor, from 2003 to 2008 for deep VLFE, from 2004 to 2012 for deep SSE, from 2003 to 2013 for shallow tremor, from 2003 to 2018 for shallow VLFE. All data were available from Slow Earthquake Database, developed by Kano et al. (2018)

3.4.3. Correspondence with interplate earthquakes

I compared the estimated mechanical locking distributions with the coseismic slip distributions of past megathrust earthquakes. Megathrust earthquakes with $> M$ 8 have repeatedly occurred every 100–150 years along the Nankai Trough (Ando, 1975; Garrett et al., 2016). The latest events occurred in 1944 (M 7.9 Tonankai Earthquake) and 1946 (M 8.0 Nankai Earthquake). The source models (coseismic slip distributions) of the two events were estimated from geodetic, seismic, tsunami, and geological records (Baba et al., 2002; Garrett et al., 2016; Murotani et al., 2015; Sagiya & Thatcher, 1999; Tanioka & Satake, 2001; Yamanaka, 2006).

Figure 3.14 shows the coseismic slip distributions of the two described events (shown as contours). I also plotted the mechanical locking distributions estimated in this study and the kinematic coupling distributions of Kimura et al. (2019). The ruptures of these two events were initiated offshore the southern Kii peninsula. The coseismic slips might be concentrated at eastern Kumano basin and off Muroto during the 1944 and 1946 events, respectively.

From the comparisons between the mechanical locking (and kinematic coupling) distributions and coseismic slip distributions, the following three features were found. First, mechanically locked distributions roughly coincide with the region where the plate interface coseismically slipped during the 1944 and 1946 earthquakes. Second, mechanically locked zones seem to be included in coseismic slip areas, rather than covering the whole coseismic slip areas, whereas kinematic high-coupled regions roughly cover (or is larger than) the whole coseismic slip areas. Third, the coseismic distribution estimated by the geodetic inversions (Sagiya & Thatcher, 1999) is slightly different to that estimated by the seismic waveform inversions (Murotani et al., 2015; Yamanaka, 2006), and the overlapping areas between the coseismic slip distributions estimated by

seismic wave inversions (Murotani et al., 2015; Yamanaka, 2006) and mechanical locking zones are larger than the overlapping areas between the coseismic slip distributions estimated by the geodetic inversions (Sagiya & Thatcher, 1999) and mechanical locking zones. The first feature demonstrates the repeatedly occurrence of the megathrust earthquake along the Nankai Trough (Ando, 1975; Garrett et al., 2016) and the recurrence potential of earthquakes in the future as suggested by previous studies, although it is difficult to predict whether mechanically locked segments would rupture simultaneously and identify the accurate coseismic slip magnitude of forthcoming earthquakes. The second feature suggests that the coseismic slip can occur not only at the mechanically locked region but also in surrounding kinematic coupled regions. During the interseismic period, shear strains may be accumulated on the mechanically locked zones. At the surrounding regions, no shear strain is accumulated owing to the constant strain condition, whereas slip deficits accompanied with the mechanical locking can be accumulated. During the earthquakes, mechanically locked zones may exhibit brittle rupturing, and the surrounding regions may be slipping accompanied by the brittle rupture. Note that, seismic wave may be radiated not only by the brittle rupture but also by the accompanying slip of the surrounding region of the brittle rupture. The moment magnitudes estimated from the geodetic inversion and the seismic waveform inversion were similar to each other (Murotani et al., 2015; Sagiya & Thatcher, 1999). The seismic waves radiating from the brittle rupture zone may dominate the short-period components, whereas the seismic waves radiating from the accompanying slip zone (surrounding the brittle rupture area) may dominate relatively long-period components. This is supported by the result in which the radiation source estimated from the short-period band-pass filtered seismic wave was partially distributed in the radiation source estimated from the long-period band-pass filtered seismic wave (Lay et al., 2012). Whether the accompanying slip propagates to the

whole interface of the kinematic high-coupled zone may depend on the seismic moment accumulated during the interseismic period. If the accumulated seismic moment is sufficiently large, coseismic slip accompanied by the brittle rupture may propagate to the region far from the rupture zone. Otherwise, the accompanying slip propagates from the rupture zone but may stop after a short period. Although it is difficult to accurately identify the spatial distributions of slip behaviors (i.e., brittle rupture or accompanied slipping) from coseismic slip distributions, the third feature described above may support the implication obtained from the second feature. Seno (2012) pointed out that the coseismic slip distributions may vary depending on the frequency-band of coseismic data used for inversions. Because seismic waveform data predominately shows shorter period signals radiated by high velocity slips, such as brittle rupturing, compared to the geodetic data, which predominately shows longer period signals, coseismic slip distributions estimated by seismic waveform inversions may be similar to the brittle rupture area. Thus, the third feature may suggest that the mechanically locked zones may be a brittle rupture during the earthquakes, supporting the implication obtained from the second feature.

I compared the hypocenters of the Nankai Trough earthquakes that occurred in 1944 and 1946 with the estimated mechanical locking distributions. The hypocenter of the 1946 Nankai Earthquake (M 8.0) appears to be located at the mechanical locking zone off Kii peninsula segment. It is difficult to distinguish whether the hypocenter is located inside the mechanical locking zone or not because the subfault size is large relative to the locking segment size. The hypocenter of the 1944 Tonankai Earthquake (M 7.9) was located 40–50 km NW from the edge of the mechanical locking zone of in the Tokai segment. In the case of the 2011 Tohoku and 2003 Tokachi earthquakes, the hypocenters of both earthquakes appeared to be located at the edge of the mechanical locking zones (Chapter 2.4.1). Thus, the 1944 Tonankai Earthquake did not seem to follow the tendency

implicated from two earthquakes in northeast Japan. One possible explanation to explain the rupture initiation of the 1944 Tonankai Earthquake is the existence of the small hidden mechanical locking zone that could not be detected by the proposed model from geodetic observation data, as is the case in Tokachi (Chapter 2.4.2). Although the spatial density of the seafloor GNSS/A observation network in this region is relatively denser compared to that of other offshore region, some tiny mechanical locking zones might not be detected.

If seismic ruptures of megathrust earthquakes are always initiated at the edges of large mechanical locking zones, the proposed model is applicable for predicting candidates of rupture initiation points of forthcoming interplate earthquakes. However, as discussed above, ruptures of megathrust earthquakes can be initiated not only at the edge of mechanical locking zone but also outside of large mechanical locking zone (perhaps at the edge of tiny mechanical locking zones). Thus, it was revealed that the new model cannot always be used to predict candidates of the rupture initiation points of future megathrust earthquakes.
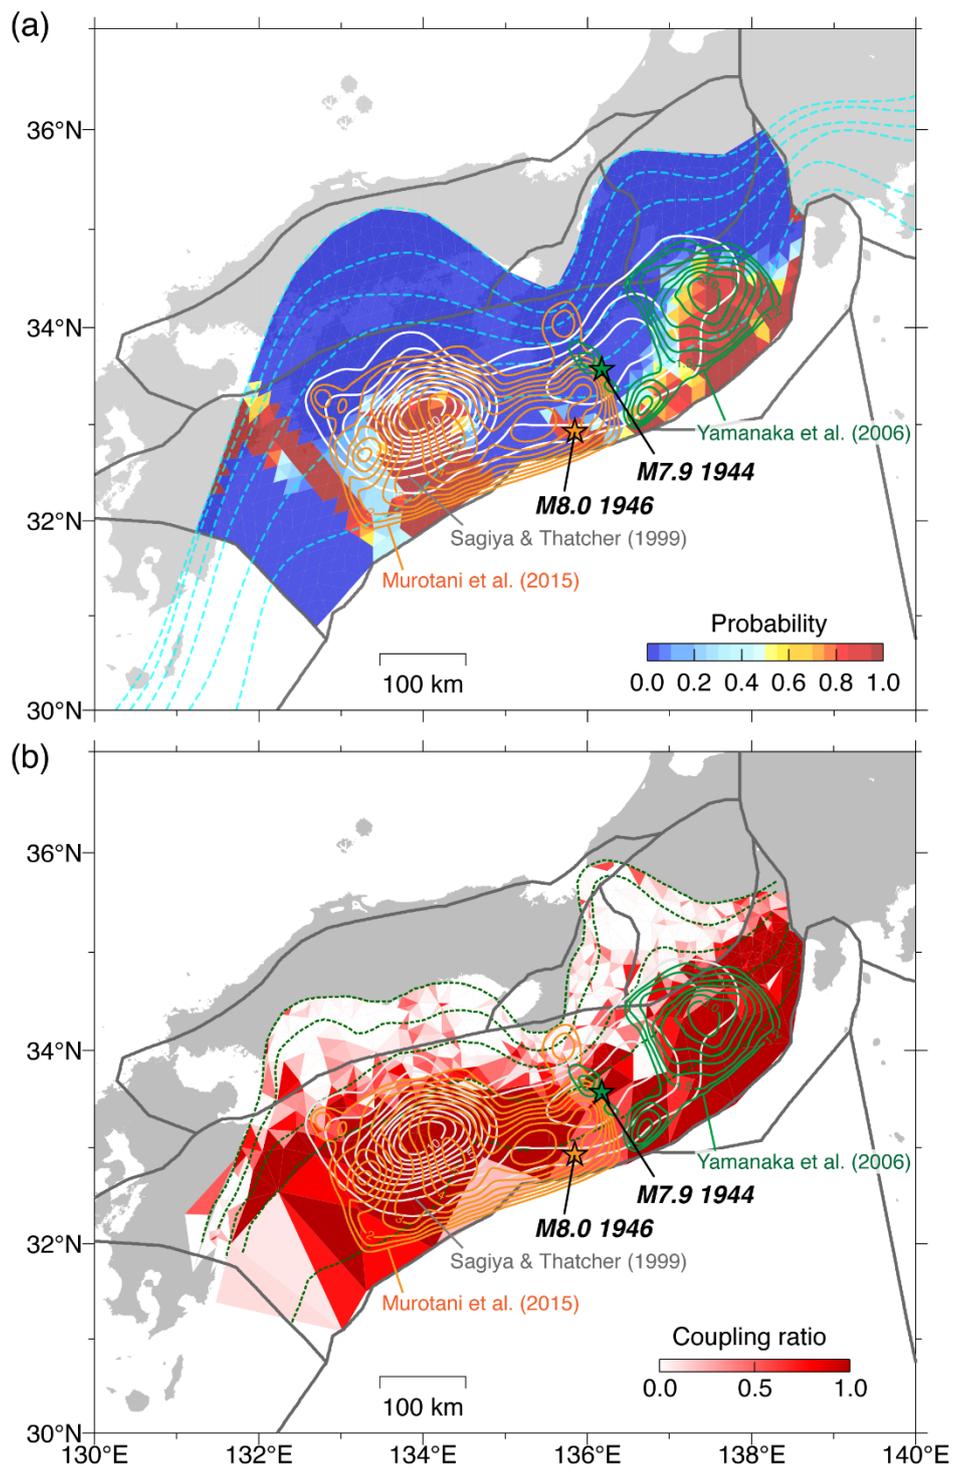

Figure 3.14. Comparison with coseismic slip area of 1944 and 1946 Nankai Trough earthquakes. Yellow stars indicate epicenters of the 1944 *M* 7.9 Tonankai and 1946 *M* 8.0 Nankai Earthquakes. These two epicenters refer to the Japan Meteorological Agency hypocenter catalogue. Coseismic slip distributions of the above two earthquakes are shown with contours. The coseismic slip distributions were estimated by seismic wave

data (Murotani et al., 2015; Yamanaka, 2006) and the geodetic observation data (Sagiya & Thatcher, 1999). (a) Map showing the coseismic slip distributions and hypocenters as well as the mechanical locking distribution. The color scale indicates the locking probability. (b) Same as (a) but as with the kinematic coupling distribution (Kimura et al., 2019). The color scale indicates the coupling coefficient.

3.4.4. Spatial relationship between mechanical locking zone and strong motion generation area

Kanda et al. (2004) estimated short-period seismic wave radiation sources from the seismic intensity inversion method based on recorded intensity data. The intensity data correlates with strong ground motion that occurred for 0.5–1 seconds and caused significant infrastructure damage (Kawase, 1998; Nozu et al., 2012). Thus, the regions of the short-period seismic wave radiation source estimated by Kanda et al. (2004) can be assumed as the SMGA. Though Kanda et al. (2004) estimated the SMGAs of four past Nankai Trough earthquakes (Hoei Earthquake in 1707, Ansei Earthquake in 1894, Showa Tonankai Earthquake in 1944, and Showa Nankai Earthquake in 1946), I focused on the latter two earthquakes because the data quality of the intensity records of the two former earthquakes is not sufficiently high.

I compared the estimated mechanical locking distributions with the SMGAs of the two earthquakes (Figure 3.15). Most SMGAs appear to be located near the edge of the mechanically locked zones excluding the northern part of the locking segment off Tokai, where the SMGA overlaps the locked zone. Similarly, SMGAs tended to be located at the edge of the mechanically locked zone in Tohoku and Tokachi in northeast Japan, as shown in Chapter 2.4.3. Thus, this spatial relationship between the SMGAs and mechanical locking zone may be a common feature for megathrust earthquakes. The physical mechanisms explaining that the SMGA is located at the edge of the mechanical locking

zone may be explained by the heterogeneity or changing of the frictional state during seismic rupture propagations. Two theories explain the short-period seismic wave radiation during the seismic rupture. The first is that rupture velocity in the coseismic slip area is heterogeneous. Miyatake et al. (2008) analytically calculated the seismic wave due to slip on the fault considering the following two cases of heterogeneities of fault parameters: heterogeneous slip magnitude with homogeneous rupture velocity and heterogeneous rupture velocity with homogeneous slip magnitude. As a consequence, Miyatake et al. (2008) concluded that the high frequency–dominant seismic wave could be effectively radiated in the rupture in which the heterogeneous rupture velocity with homogeneous slip magnitude was imposed compared to the rupture in which the heterogeneous slip magnitude with homogeneous rupture velocity was imposed. The heterogeneity of the rupture velocity considered in Miyatake et al. (2008) can be assumed to be a heterogeneity of the slip velocity because the rupture velocity is proportional to the maximum slip velocity (Ida, 1973). Thus, the high frequency-dominant seismic wave may be effectively radiated by the rupture with the heterogeneous slip velocity. The second one is the abrupt decreases in the rupture velocity (sometimes called a "stopping phase") during rupture propagation. Bernard & Madariaga (1984) calculated displacement waveforms during the rupture with a simple crack model and suggested the discontinuity of the displacement waveform (and thus the abrupt changes of velocity and acceleration waveforms) when the rupture stopped at the edge of the crack. They concluded that abrupt changes in velocity and acceleration waveforms may cause the radiation of short period dominant waveforms. It is common that slip velocity is changing during the rupture propagation in the above two mechanisms, though these mechanisms are different to each other. According to the rate- and state-dependence frictional law (Dieterich, 1979), the slip velocity may be controlled by the frictional states on the plate

interface. Frictional states on the plate interface may vary between mechanically locked and creeping zones, as discussed in Chapter 3.4.2: mechanically locked zones coincide with frictionally locking (or unstable sliding) fields, whereas the creeping zones coincide with the conditionally stable sliding or stable sliding fields. Thus, when the rupture propagates through the edge of the mechanical locking zones, frictional states change, and the slip velocity may abruptly increase or decrease. As a consequence, the short-period seismic waveform is radiated.

As mechanical locking zone size increases, the area where SMGAs can be located may increase as well considering the implication presented above (i.e., that SMGAs may be located at the edges of mechanical locking zones). The mean size of the mechanical locking zones estimated along the Nankai Trough is larger than that estimated along the Japan Trench (Figure 3.16). Thus, the possible areas where SMGAs can be found may be larger along the Nankai Trough compared to along the Japan Trench. It is important to predict SMGAs for effective earthquake disaster mitigation. The mechanical locking distributions estimated by geodetic observation data on the basis of the new physical model developed in this study may be useful for predicting SMGA candidates of forthcoming megathrust earthquakes.
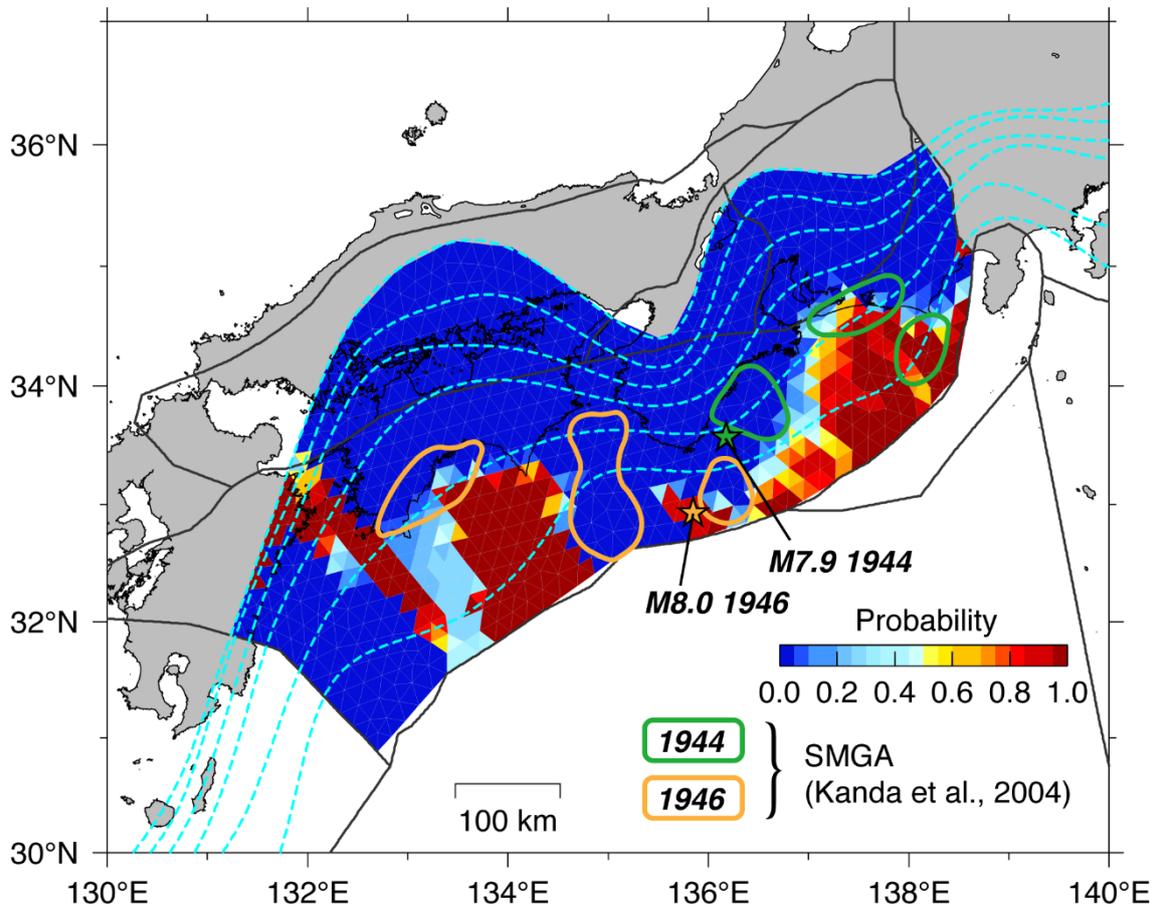

Figure 3.15. Map showing strong motion generation areas of the 1944 *M* 7.9 Tonankai Earthquake (cyan closed line) and 1946 *M* 8.0 Nankai Earthquake (yellow closed line) estimated from seismic intensity records (Kanda et al., 2004). The background color scale indicates mechanical locking distributions expressed as locking probability.
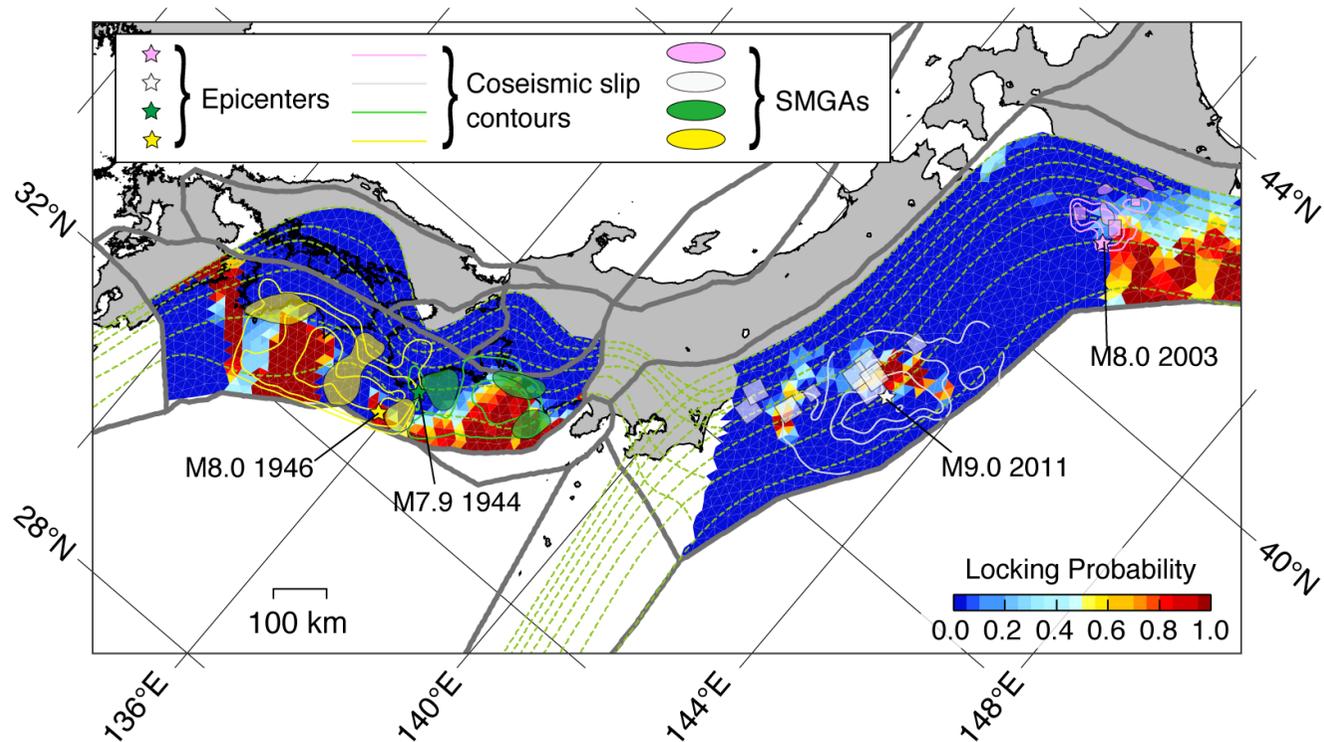

Figure 3.16. Map showing mechanical locking distributions, epicenters, coseismic slip distributions, and SMGAs along the Nankai Trough and Japan and Kuril Trench. Background color represents locking probability. Colored stars, contour lines, and enclosed area indicate epicenters, coseismic slip distributions (Murotani et al., 2015; Yamanaka, 2006; Yamanaka & Kikuchi, 2003; Yokota et al., 2011), and SMGAs (Kamae & Kawabe, 2004; Kanda et al., 2004; Kurahashi & Irikura, 2013; Nozu & Irikura, 2008), respectively, of past megathrust earthquakes. Pink, light gray, green, and yellow coloring corresponds to the 2003 Tokachi (*Mw* 8.0), 2011 Tohoku (*Mw* 9.0), 1944 Tonankai (*M* 7.9), and 1946 Nankai (*M* 8.0) earthquakes, respectively. Dashed lines indicate iso-depth contours with 10 km depth intervals. Gray lines indicate block boundaries.

124

3.4.5. Comparison with subducted topographic anomalies

In the previous sections, I focus on the relation between mechanical locking distributions and the frictional state on the plate interface, and it was suggested that mechanically locked zones coincide with frictionally locked (unstable sliding or stick slip) zones. In this chapter, I focus on the relation between mechanical locking distributions and topographic anomalies of the subducted plate.

Figure 3.17 shows four major topographic anomalies—Paleo Zenisu ridge (Park et al., 2004), high-density buried rock (Kaneda et al., 2006), Muroto seamount (Kodaira et al., 2002), and Kyushu–Palau ridge (Park et al., 2009)—of subducted plate interface along the Nankai Trough. As illustrated in Figure 3.17, no obvious correlation between the mechanical locking and subducted topographic anomaly distributions was observed found. Muroto seamount, high-density buried rock off Kii peninsula; the Kyushu–Palau ridge appears to be located in regions exhibiting low or near-zero locking probabilities, while the paleo Zenisu ridge overlaps the mechanically locked zone in the Tokai segment. This suggests that the subducted topographic anomalies can cause both mechanical locking and creeping (mechanically unlocked). Previous studies suggested that topographic anomalies controlling the slip propagation during the earthquake should be mechanically locking (Kodaira et al., 2002). However, this hypothesis may not explain all observed phenomena because the frictional strength on the plate interface of the subducted seamount can be decreased by pore fluid. Shallow slow earthquakes were detected in the region where the Muroto seamount subducts (Figure 3.13 and 3.17). The occurrence of shallow slow earthquakes is considered to be related to elevated pore fluid pressure on the plate interface (Araki et al., 2017). Significantly low shear wave velocity was estimated from the seismic exploration survey data at the region where the subducted

Muroto seamount was found, implying the existence of fluid on the plate interface (Tonegawa et al., 2017).

The comparison indicates that whether the plate interface is mechanically locked may be controlled by frictional states rather than by the subducted topographic features. To understand mechanical locking distributions on the plate interface, it was considered more useful to apply the proposed model developed to the geodetic observation data rather than conduct a structural survey beneath the seafloor.
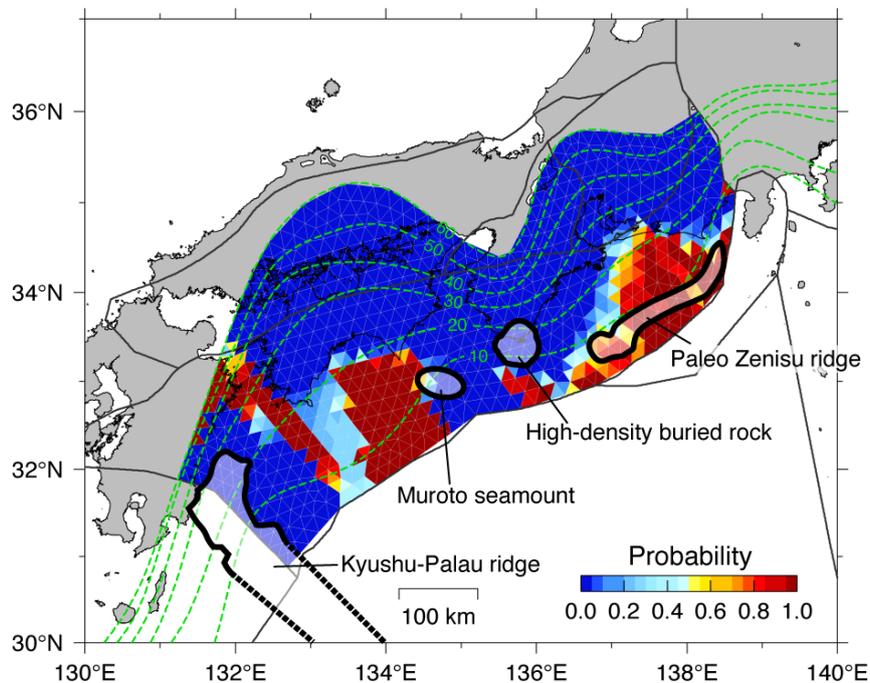

Figure 3.17. Map showing the surface tracing of major topographic anomalies on the subducted plate interface and mechanical locking distributions expressed as the locking probability along the Nankai Trough. The following are references for each topographic anomaly: Paleo Zenisu ridge, Park et al. (2004); High-density buried rock, Kaneda et al. (2006); Muroto seamount, Kodaira et al. (2002); Kyushu–Palau ridge Park et al. (2009).

3.5. Chapter summary

The proposed model discussed in the previous chapter was applied to southwest Japan to estimate mechanical locking distributions along the Nankai Trough from onshore GNSS and seafloor GNSS/A observation data.

Estimated mechanical locking distributions were compared with kinematic coupling distributions estimated by Kimura et al., (2019) in which the same dataset and block configurations were used. Moreover, estimated mechanical locking distributions were compared with slow earthquake distributions, coseismic slip distributions, hypocenters, and SMGAs of Showa Nankai Trough earthquakes in 1944 and 1946, and subducted topographic features. The following main results and implications were derived from the findings presented in this chapter.

- Four mechanical locking segments exist at Hyuganada, Shikoku, Kii peninsula, and Tokai.

- Mechanical locking zones are notably smaller than kinematic high-coupling zones. High slip deficits at regions exhibiting low locking probabilities occur due to mechanical locking in adjacent regions.

- Spatial complementation between the mechanical locking zone and slow earthquake occurrence zones was clearly observed. This suggests that estimated mechanical locking distributions indicate frictional states on the plate interface, even if physical parameters were not considered in the proposed model.

- Coseismic slip areas of Showa Nankai Trough Earthquakes are larger than mechanical locking zones but almost equal to the kinematic high-coupling areas. Moreover, estimated mechanical locking zones are similar to the coseismic slip areas estimated from the seismic waveform data rather than to those estimated from the geodetic data. This implies that mechanical locking zones correspond to brittle

rupture zones and that kinematic high-coupled but mechanically unlocked (creeping) zones correspond to the accompanying slip zones.

- SMGAs tend to be located at the edge of mechanically locked zones. Potential SMGAs are larger along the Nankai Trough than along the Japan Trench. Short-period seismic wave radiation may be caused by rupture propagations throughout the region where frictional properties significantly vary.

- There is less correlation between subducted topographic features and mechanical locking distributions. Even if remarkable topographic features exist on the plate interface, frictional states that can control mechanical locking states vary due to other physical processes, such as pore fluid pressure elevation.

Chapter 4
Conclusions

In this study, a novel physical model was developed that describes the relation between mechanical locking on the plate interface and surface crustal deformations to estimate mechanical locking distributions on the plate interface using geodetic observation data.

The mechanical locking distributions along the Japan and Kuril Trenches and along the Nankai Trough were estimated by adopting this physical model with onshore GNSS and seafloor GNSS/A observation data observed at the interseismic periods using the REMC method. Estimated mechanical locking distributions were compared with kinematic coupling and coseismic slip distributions, hypocenters, and SMGAs. Additionally, estimated mechanical locking distributions were compared with slow earthquake distributions and subducted topographic anomalies along the Nankai Trough. Figure 4.1 shows the schematic image of mechanical locking and slip behaviors on the plate interface along the Japan and Kuril Trenches and along the Nankai Trough.

It was found that mechanical locking zones were distributed as segments in both subduction zones. This suggests the trench-parallel heterogeneity of frictional properties of the plate interface because the mechanical locking zones coincide with frictional locking (unstable field) owing to notable spatial complementation between mechanical locking zones and slow earthquake occurrence zones. Although previous studies have revealed the trench-parallel heterogeneity of the slip deficit rate using geodetic inversions based on pure kinematic models, this study is the first to reveal the trench-parallel heterogeneity as a frictional heterogeneity with a geodetic approach. Because the frictional property can control the slip behaviors on the plate interface during earthquakes (or earthquake cycles), revealing the frictional distributions on the plate interface by

estimating the mechanical locking distributions using the proposed model can facilitate improved prediction of slip behaviors during earthquakes, which is essential for evaluating the occurrence potential of future megathrust earthquakes.

The mechanical locking area was included in the kinematic high-coupling area both along the Nankai Trough and along the Japan and Trench. The mechanical locking zones coincide with kinematic high-coupling regions, but the reverse is not always true. High slip deficits can be produced in creeping (mechanically unlocked) zones via mechanical locking at the adjacent regions. Particularly, the slip deficit become high in creeping zones between two mechanical locking segments. The proposed model was determined useful for detecting mechanical locking zones in such cases. However, it is difficult to detect small mechanical locking zones (such as those that are hidden and may have caused the 2003 Tokachi earthquake) using the new model. Developing a robust and accurate geodetic observation network on the seafloor as well as onshore may overcome this limitation.

SMGAs tend to be located at the edge of the mechanical locking zone both along the Nankai Trough and along the Japan Trench. Radiations of short-period dominant seismic waves at the edges of mechanical locking zones may be explained by abrupt changes in plate interface properties, such as unstable fields in mechanical locking zones and stable sliding fields in creeping zones. Potential SMGAs were suggested to be larger in the Nankai Trough compared to those along the Japan Trench because the size of the mechanical locking zone is notably larger along Nankai Trough compared to along the Japan Trench.

The locking state at the shallowest part of the plate interface differed between regions along the Nankai Trough and Japan Trench. The shallowest part of the plate interface was estimated to be mechanically locked along the Nankai Trough but mechanically unlocked

along the Japan Trench. Geological conditions, such as consolidation degrees of the sedimental layer or =localized topographic anomalies, at the toe portion of subduction zones may control the mechanical locking condition. Alternatively, the strain accumulation at the splay faults in accretionary prisms could be estimated to the mechanical locking on the plate interface, which this study did not consider. Numerous splay fault systems in accretionary prisms have been identified by geophysical surveys along the Nankai Trough (e.g., Park & Kodaira, 2012; Tsuji et al., 2014). The possibility of tsunami generation due to the slip of splay faults during the 1946 Nankai earthquake has also been reported (e.g., Cummins et al., 2001). To evaluate the tsunami potential of future megathrust earthquakes, accurate estimations of mechanical locking distributions not only along the plate interface but also along splay faults may be required. To realize this, denser and more accurate seafloor geodetic observations are necessary to improve the accuracy of derived offshore detailed crustal displacement fields, particularly in regions where splay faults are observed.

Some common features, such as segmented mechanical locking distributions, the spatial relationship between the mechanical locking distributions, coseismic slip distributions, and SMGAs, between different subduction zone types (i.e., Japan and Kuril Trench and Nankai Trough) identified using factors such as dip angle, convergence rate, and temperatures imply that the proposed model can effectively predict brittle rupture areas, coseismic slip areas, and SMGA candidates for future megathrust earthquakes. The ability to predict these factors can promote effective earthquake disaster mitigation. Particularly, predicting SMGA candidates may be useful simulating strong ground motions. There are many subduction zones where megathrust earthquakes have occurred, such as those in Kamchatka, Alaska, Chile, Indonesia, and New Zealand. The proposed method may be useful in the region where the interseismic geodetic observation data is

available for estimating mechanical locking (frictional state) distributions and thus predicting brittle rupture zones, accompanying coseismic slip zones, and SMGA candidates for future megathrust earthquakes globally. In addition, applying this model to inland block boundaries may enable researchers to estimate mechanical locking distributions at inland faults, which will contribute to the advanced evaluation of the seismic potential of inland earthquakes.

Appendix A
Rigid motion and internal block strain results: Northeast Japan

A.1. Estimated Euler vectors and calculated rigid motions

Figure A.1(a) depicts the rigid motion component of the surface velocities at the onshore and seafloor sites calculated by Euler vector estimates (Table A.1) relative to the Eurasian Plate. Velocities plotted on the subducting Pacific Plate were based on the MORVEL plate model (DeMets et al., 2010). Almost all overriding blocks move in a west or west–northwest direction. The displacement rates were higher in the forearc side blocks (12–15 mm/yr on average), such as the Tohoku Forearc block, than in the backarc side blocks (5–10 mm/yr on average). The Pacific Plate subduction rate at the Kuril and Japan Trenches was approximately 76–78 mm/yr. This velocity was slightly lower than that of previous studies (DeMets et al., 2010; Loveless & Meade, 2010). Although the relative block motion rates were less than 5 mm/yr for most block boundaries, this study found fast relative motions in some boundaries. Between the Okhotsk and the Tohoku Forearc blocks, a 5–8 mm/yr compression (boundary–normal direction) and a 5–8 mm/yr right lateral (boundary–parallel direction) motion were estimated. Between the Tohoku Forearc and the Tohoku Backarc blocks, a 3–7 mm/yr compression was estimated. This boundary corresponds to the Ou Backbone Range, which is characterized by a reverse fault zone, and has been known as a geodetically high strain rate zone (Miura et al., 2002; Toya & Kasahara, 2005). The estimated compression consists of the high geodetic strains. Between the southern part of the Tohoku Backarc and the Niigata blocks, called the NKTZ, a 2–10 mm/yr compression and a 3–7 mm/yr right lateral motion were estimated. GNSS observations show a large velocity gradient for compressional direction near the

boundary (Figure **2.2**). This compression represents strain concentration at and/or around the boundary. Some models were presented to explain high strain rates around the boundary. Hyodo & Hirahara (2003) considered the interplate coupling on the subducting Pacific Plate interface and the localized viscoelastic layer in the elastic crust. Nishimura et al. (2012) explained this by dislocation in the crust deeper than the seismic zones and viscoelastic response considering gravity.

Table A.1. List of Euler vector estimates. All Euler vectors are relative to the Eurasian plate. Positive angular velocities indicate counterclockwise rotation. Pole location and angular velocity of the Pacific Plate area refer to the MORVEL plate model (DeMets et al., 2010). Covariances are Cartesian and have units of 10^{-8} rad^2/Myr^2.

Figure A.1. Map showing calculated vectors and relative motion rates. Black and red arrows depict the rigid motion rate and elastic response from interplate slip deficits, respectively. The reference for rigid motion is the Eurasian plate. The color scale shown along the block boundary line represents the relative block motion rate.

A.2. Estimated internal block strains

In Figure A.1(b), the internal strain rate of each block is plotted with green cross vectors, the surface trace of active faults (Nakata & Imaizumi, 2002) with red lines, and the inland earthquake mechanisms with colored circles. Table S2 also lists internal block strain results. Because the study did not estimate the subducting and internal block strain rates (i.e., of the Pacific Plate and Izu–Ogasawara blocks), the figure and table for the two blocks do not show these results. The focal mechanisms plotted in the figure were observed by the F-net Broadband Seismograph Network maintained by the National Research Institute for Earth Science and Disaster Resilience (Okada et al., 2004).

The magnitude of principal strain rates seems to be larger (~20–27 nanostrain/yr) in Hokkaido, which is the southern part of the Okhotsk plate, than those in other blocks. Considering that a remarkable intraplate earthquake has not occurred in this block, the estimated strain may reflect long-term stress field formed by geological processes. Hokkaido is located in a strong deformation area owing to large-scale collisions in the Eastern Japan Sea deformation zone (Nakamura, 1983; Le Pichon et al., 1998), the convergence of the Okhotsk plate in central Hokkaido (Kato et al., 2004; Komatsubara, 2015), and the collision of the Kuril forearc sliver at the Hidaka Mountain (Kimura, 1996; Kimura & Kusunoki, 1997). The combination of these stress fields may be qualitatively expressed as the estimated strain when the uniform strain field in a block is assumed.

In the Tohoku Forearc block, 16 nanostrain/yr of compressional strain with an azimuth of 120 degree was estimated. This compressional direction is roughly perpendicular to the strike of the predominant reverse fault and consistent with the P-axis of the focal mechanism in the block, particularly in central Tohoku. The surface displacement rate calculated from the strain rate was less than 3.7 mm/yr, which was 22–25% of the mean rigid motion and elastic response from the interplate slip deficit.

138

In the Niigata block, the largest compressional strain was 15 nanostrain/yr with a roughly north–south orientation azimuth. The compressional strain was also estimated as another principal strain, and the magnitude was less than half of the largest one. The estimated largest compressional strain in this block was not consistent with both the P-axis of most focal mechanisms and strain fields estimated from the onshore geodetic observation data (Sagiya, 2004; Sagiya et al., 2000). This paradox may have been caused by the location of the block boundary, the treatment of the heterogeneous strain field, and the long-term geologically accumulated strain. Fortunately, because this block is sufficiently far from the forearc side of Tohoku and Hokkaido, where the surface crustal deformation would be affected by the mechanical locking on the subducting Pacific Plate interface, the mechanical locking distribution estimates on the plate interface would not be affected by the crustal deformation data and/or strain rate estimates in the Niigata block.

Table A.2. List of internal block strain estimates. Normal strain rates area measured as extensional positive. Reference points of each block are centroids of the observation site network within each block.

Block	Reference points		Principal strain rates				Uncertainties			
	Lat. (°N)	Lon. (°E)	Maximum normal strain (10^{-9}/yr)	Minimum normal strain (10^{-9}/yr)	Direction of the minimum strain (°)	Maximum shear strain (10^{-9}/yr)	Maximum normal strain (10^{-9}/yr)	Minimum normal strain (10^{-9}/yr)	Direction of the minimum strain (°)	Maximum shear strain (10^{-9}/yr)
Amurian	34.759	132.836	14.5	-17.7	193.4	16.1	3.8	2.6	6.7	2.3

Figure A.2. Map showing principal strain rates calculated from estimated internal block strain rates. Green cross arrows indicate principal strain rates. The locations where strain crosses are plotted are reference points, which are the centroid of the observation site network within each block. Red lines are active fault tracings (Nakata & Imaizumi, 2002). The black and white circles indicate earthquake epicenters and mechanisms. Earthquakes that occurred offshore the Pacific Plate side were removed from the figure. Mechanism data were provided by the F-net broadband seismograph network maintained by the NIED (Okada et al., 2004). The data period, magnitude range, and lower depth limit are 1997–2010, 3–7.5, and 20 km, respectively.

Appendix B
Rigid motion and internal block strain results: Southwest Japan

B.1. Estimated Euler vectors and the ratio between rigid motion and displacement due to slip deficit

The estimated Euler vector and its covariance are shown in Table B.1. I calculated the rigid motion rates at the observation sites on the basis of estimated Euler vectors (Figure B.1(a)). Because the rigid motion of Amurian plate was fixed to zero in the REMC inversion, plotted rigid motion rates are relative to Amurian plate. Surface displacements rate due to slip deficits on the plate interface were also calculated and shown in the same figure. The colored line along the block boundary indicate the relative block motion rate, which was calculated as $\sqrt{v_{\text{str}}^2 + v_{\text{ext}}^2}$, where the v_{str} and v_{ext} represent strike slip and extension rates of the relative motion along the block boundary, respectively.

The direction of the rigid motion is WSW and WNW dominant in most blocks excluding the Okinawa-North block in which southward rigid motion was calculated from the estimated Euler vector. The rigid motion rate of the forearc side is higher than that of the backarc side, which is the same as the northeast (Chapter A.1). The average rigid motion rates in each block are shown in Figure B.1(a) are 15 (Nankai block), 10 (Okinawa-North block), 10 (Kinki block), 13 (Chubu block), 28 (Izu Micro Plate), 42 (Izu–Ogasawara block), 15 (Okhotsk plate), and 2 mm/yr (Setouchi block).

The plate (block) convergence rates along the Nankai Trough differ significantly between western and eastern sides at 50–54 mm/yr in western side (i.e., along the boundary between Philippine Sea Plate and Nankai block) and 19–20 mm/yr in eastern side (i.e., along the boundary between Izu Micro Plate and Nankai block). This

convergence rate contrast caused the slip deficit rate to contrast between western and eastern sides of the plate interface along the Nankai Trough (Chapter 3.3). Because of this, the surface displacement rate is dominated with the displacement rate due to interplate slip deficits rather than the rigid motion rate in the western Nankai block (velocity ratio between the rigid motion and the displacement due to the interplate slip deficits is approximately 0.3–0.7), whereas the rigid block motion rates are comparable to or larger than the displacement rates due to the interplate slip deficits in eastern Nankai block.

The Philippine Sea Plate subducts (or collides) beneath the Izu Micro Plate. The convergence rate at the boundary between Philippine Sea and Izu Micro Plates is 28–29 mm/yr, which is higher than the convergence rate between Izu Micro Plate and Nankai block. Along the boundary, remarkable topographic feature called the Zenisu ridge exists. Although this study did not focus on this boundary because of poor geodetic observations and unclear tectonic boundary settings around the boundary, seismic potential accompanying huge tsunami was proposed in few models (e.g., Nakata et al., 2013). Thus, it may be an urgent task to develop a seafloor geodetic observation network as well as to reveal the accurate subsurface structure by seismic exploration for the evaluation of seismic and tsunami hazard around Zenisu ridge.

Relatively rapid relative motion was found along some inland block boundaries, including that between Nankai and Setouchi blocks. This boundary corresponds to the western part of the Median Tectonic Line. The relative motion rate along the boundary was ~10 mm/yr, coinciding with the average slip rate of 5–10 mm/yr that was estimated on the basis of the regional dense GNSS observations conducted around the Median Tectonic Line in Shikoku (Tabei et al., 2002, 2003). The others are boundaries between Kinki and Setouchi blocks, Chubu and Setouchi blocks, and Chubu block and Amurian

plate. These boundaries can be connected with the block boundary that is between Niigata and Tohoku Backarc blocks (Chapter A.1), where the relatively fast relative motion rate was found in northeast Japan. As described in Chapter A.1, these boundaries correspond to the Niigata–Kobe Tectonic Zone (e.g., Sagiya et al., 2000), and some models were presented to explain high strain rates around the boundary, such as the interplate coupling on the Pacific Plate interface and the localized viscoelastic layer in the elastic crust (Hyodo & Hirahara., 2003), dislocation in the crust deeper than the seismic zones and the viscoelastic response considering gravity (Nishimura et al., 2012).

Table B.1. List of Euler vector estimates. All Euler vectors are relative to Amurian plate. Positive angular velocities are counterclockwise rotation. Pole location and angular velocity of Pacific and Yangtze plates are fixed to the value presented by MORVEL plate model (DeMets et al., 2010), and they were not estimated in this study. Covariances are Cartesian and have units of 10^{-8} rad^2/Myr^2.

Block	Angular velocity			Variances and covariances					
	Lat. (°E)	Lon. (°N)	ω (deg/Myr)	σ_{xx}	σ_{xy}	σ_{xz}	σ_{yy}	σ_{yz}	σ_{zz}

Figure B.1. Map showing the calculated displacement rates. Black and red arrows depict the rigid motion rate and elastic response from interplate slip deficits. The reference for rigid motions is the Amurian plate. The color scale shown along the block boundary line represents relative block motion rate.

B.2. Estimated internal block strains

The estimated strain rate in each block was listed in Table B.2. I calculated the principal strain rates from the estimated strain rate $\dot{e}_{xx}$, $\dot{e}_{xy}$, and $\dot{e}_{yy}$ and plotted with green cross vectors in Figure B.1(b). The surface trace of active faults (Nakata & Imaizumi, 2002) and the inland earthquake mechanisms were also respectively plotted with red lines and colored circle in the same figure. Because the strain rates of Philippine Sea, Pacific and Yangtze plates were not estimated (fixed to zero), the figure and table for the three blocks do not show these results. The focal mechanisms plotted in the figure were observed by the F-net Broadband Seismograph Network maintained by NIED (Okada et al., 2004).

Compressional strains with WNW to NNW directions were estimated in Nankai, Setouchi, Kinki, and Chubu blocks and Amurian plate, those are overriding bocks of southwest Japan. The estimated magnitude of the strain rate was estimated on the order of 10^{-9}–10^{-8}/yr. Relatively higher strain rates were estimated in Nankai (3.2×10^{-8}/yr of compression with the axis of N53° W) and Chubu (2.4×10^{-8}/yr of compression with the axis of N62° W) blocks. For overriding blocks, many intraplate earthquakes occurred in the blocks and along the inland bock boundaries (Figure B.1(b)). The mechanism of these intraplate earthquakes exhibited mainly strike slip, except for few events, which exhibited reverse fault type occurred near Ise bay and western Wakayama prefecture. However, the mechanism expected from the estimated strain rates in these blocks may be reverse fault type with the P axis of WNW–NNW direction, which conflicts with the dominant mechanisms in these blocks. Instead, the compressional strain orientation is close to the subducting direction of the Philippine Sea and Izu Micro Plates. In the new model developed in this study, only the shear stress working on the plate interface and the displacement due to the shear strain were considered. Thus, the displacement due to the

normal stress working on the plate interface may be estimated as the compressional strain with the plate subducting direction.

Table B.2. List of internal block strain estimates. The unit of strain rates is 10^{-9}/yr. Normal strain rates area measured as extensional positive. Reference points of each block area centroid of the observation site network within each block.

Block	Reference points		Principal strain rates				Uncertainties			
	Lat. (°N)	Lon. (°E)	Maximum normal strain (10^{-9}/yr)	Minimum normal strain (10^{-9}/yr)	Direction of the minimum strain (°)	Maximum shear strain (10^{-9}/yr)	Maximum normal strain (10^{-9}/yr)	Minimum normal strain (10^{-9}/yr)	Direction of the minimum strain (°)	Maximum shear strain (10^{-9}/yr)

Figure B.2. Map showing the principal strain rates calculated from the estimated internal block strain rates (Table B.2). Green cross arrows are the principal internal block strain rates. The locations where the strain crosses are plotted is the reference point, which is the centroid of the observation site network within each block. Note that the actual centroid location of the observation network included in the Amurian plate is located at the point outside of the Amurian plate and near the centroid location of the Setouchi block. To avoid that one may confuse to recognize the strain rates of Setouchi block and Amurian plate, the principal strain rate cross of the Amurian plate were replotted inside of the Amurian plate. Red lines are active fault tracings (Nakata & Imaizumi, 2002). The black and white circles indicate the earthquake epicenters and mechanisms. Earthquakes that occurred offshore of the Pacific Plate side are removed from the figure. The mechanism data were provided by the F-net broadband seismograph network maintained by the NIED (Okada et al., 2004). The data period, magnitude ranging, and lower depth limit are 2006–2009 3–6, and 20 km, respectively.

Appendix C
Displacement rate data for REMC inversion

This chapter provides tables listing the displacement rate data used for REMC inversions. In each table, code (number or name), location in longitude and latitude, EW, NS, and UD components of the displacement rate, and their uncertainties are provided. The height of sites was fixed to 0 km. The UD component of the displacement rates and its uncertainties of seafloor GNSS/A sites was not estimated and thus not listed in the following tables.

C.1. Northeast Japan

Table C.1. List of displacement rates at onshore and seafloor observation sites in northeast Japan used in the analysis outlined in Chapter 2. The reference frame is the Eurasian plate, taken from the MORVEL plate motion model (DeMets et al., 2010).

C.2. Southwest Japan

Table C.2. List of displacement rates at onshore and seafloor observation sites in southwest Japan used in the analysis of Chapter 3. The reference frame is Amurian plate of MORVEL plate motion model (DeMets et al., 2010).

Site	Site position		Displacement rate (mm/yr)			Uncertainties (mm/yr)		
	Lon. (°E)	Lat. (°N)	EW	NS	UD	EW	NS	UD
841	139.070	34.950	-32.95	4.66	1.01	0.06	0.05	0.17
