58 **Abstract**

59 To overcome the delayed or failed engraftment after unrelated cord blood transplantation
60 (CBT), we conducted a multicenter phase II study of intrabone single-unit CBT without
61 antithymocyte globulin (ATG) for adult patients with hematological malignancies
62 (UMIN-CTR, UMIN000020997). Sixty-four patients received an intrabone injection of
63 unwashed (n = 61) or washed (n = 3) cord blood after local anesthesia. All injection-related
64 adverse events were mild and resolved spontaneously. Sixty-two patients were evaluable
65 for the efficacy of intrabone CBT of serological HLA-A, -B, and -DR $\geq 4/6$ matched cord
66 blood with a median number of $2.57 \times 10^7/\text{kg}$ cryopreserved total nucleated cells. The
67 probability of survival with neutrophil engraftment on day 28 was 77.4% (95% confidence
68 interval, 67.0–85.8%), which exceeded the threshold value. The cumulative incidences of
69 neutrophils $\geq 0.5 \times 10^9/\text{L}$ on day 60 was 80.6% (68.2–88.6%), with a median time to
70 recovery of 21 days after transplantation. The cumulative incidences of platelets $\geq 20 \times$

71 $10^9/L$ and platelets $\geq 50 \times 10^9/L$ on day 100 were 75.8% (62.6–84.9%) and 72.6% (59.4–
72 82.1%), respectively, with median time to platelets $\geq 20 \times 10^9/L$ and platelets $\geq 50 \times 10^9/L$ of
73 38 and 45 days after transplantation, respectively. The cumulative incidences of grade II–IV
74 and III–IV acute graft-versus-host disease were 29.0% and 6.5%, respectively. All
75 responded to steroid therapy, and secondary treatments were not required. The present
76 study suggests the efficacy of intrabone single-unit CBT without ATG in terms of early
77 engraftment and controllable acute graft-versus-host disease.

81 **Introduction**

82 Although hematopoietic cell transplantation (HCT) from an HLA-haploidentical related
83 donor has been increasingly selected as a treatment for patients with hematological
84 malignancies who lack HLA-matched related or unrelated donors, cord blood
85 transplantation (CBT) is still an attractive option, particularly when immediate
86 transplantation is needed [1, 2]. Overall survival or leukemia-free survival after CBT is
87 comparable to those after bone marrow transplantation (BMT) and peripheral blood stem
88 cell transplantation (PBSCT) from HLA-matched unrelated donors [3–4]. However,
89 delayed or failed engraftment is a serious concern in CBT. The incidence of graft failure
90 has been reported to be approximately 20% after CBT, compared to approximately 5–10%
91 and 5% after unrelated BMT and PBSCT, respectively [3–5]. Various attempts have been
92 made to minimize this disadvantage of CBT. As the dose of cryopreserved total nucleated
93 cells (TNC) and CD34+ cells are major determinants of engraftment, double cord blood

94 units have been widely used as transplant sources [6–8]. However, prospective randomized
95 studies have demonstrated similar engraftment rates between double-unit CBT and
96 single-unit CBT with an adequate cell dose [9, 10]. Expansion of cord blood cells ex vivo
97 before transplantation has been developed to increase the number of transplanted cells [11,
98 12]. A recent phase I/II study of CBT with a single cord blood unit, which was expanded
99 ex-vivo in the presence of nicotinamide, showed promising results [13], although this
100 specialized technique cannot be universally adopted.

101 Intrabone CBT was established by Frassoni F et al., to reduce loss of cord blood cells
102 which might be trapped in other organs after intravenous injection, and to enhance the
103 homing of stem cells to the bone marrow [14]. This strategy requires neither an additional
104 cord blood unit nor specialized technique or cell-processing facility. Their study and
105 subsequent four prospective studies reported good tolerability and potential to enhance
106 engraftment of intrabone CBT [15–18]. In fact, most studies demonstrated neutrophil

107 engraftment rates of more than 80% in adult patients after intrabone single-unit CBT [14,
108 16–18]. It is note that, in these studies, the engraftment rate was defined as a cumulative
109 incidence of neutrophil recovery $\geq 0.5 \times 10^9/L$ on day 60–100. This is in contrast to BMT
110 and PBSCT, in which presence or absence of engraftment is usually assessed on day 21–28
111 and if no elevation of neutrophil count is observed by day 28, the patients are considered
112 for a second infusion of stem cells from the original donor or retransplantation from a
113 different donor [19–21]. As we mentioned above, the intrabone CBT is attractive in terms
114 of the enhancement of engraftment, however there is little direct evidence to support the
115 hypothesis that the intrabone CBT improves engraftment rate at a very early time, such as
116 28 days after transplantation.

117 Therefore, a multicenter phase II study of intrabone single-unit CBT without ATG for
118 adult patients with hematological malignancies was conducted to assess the probability of
119 survival with neutrophil engraftment on day 28 after transplantation.

120

121 **Materials and Methods**

122 **Patients**

123 From June 2016 to September 2018, 66 patients were enrolled in this study at 10 institutes
124 in Japan: Nagoya University, Tokyo Metropolitan Cancer and Infectious Diseases Center
125 Komagome Hospital, Anjo Kosei Hospital, Japanese Red Cross Narita Hospital, Niigata
126 University Medical and Dental Hospital, Tohoku University, Okayama University, Hyogo
127 College of Medicine, Hokkaido University, and Shizuoka Cancer Center. Eligible patients
128 had hematological malignancy and needed CBT. Patients were required to be aged ≥ 16 , to
129 have an Eastern Cooperative Oncology Group performance status of 0, 1 or 2, to have
130 adequate liver, kidney, lung, and heart functions, and to have available serological HLA-A,
131 -B, and -DR $\geq 4/6$ matched cord blood with a cryopreserved TNC at least $2 \times 10^7/\text{kg}$. The
132 study was approved by the ethics committees at each institute, and written informed

133 consent was obtained from each patient in accordance with the Declaration of Helsinki. The
134 study has been registered at UMIN-CTR as UMIN000020997.

135

136 **Transplantation**

137 Conditioning regimens and supportive care were assigned according to each institutional
138 protocol at the clinical sites. Cyclosporine (CsA) or tacrolimus (Tac) with short-term
139 methotrexate (MTX) or mycophenolate mofetil (MMF) were used for prophylaxis of
140 GVHD. ATG was not used as GVHD prophylaxis.

141

142 **Procedure of intrabone injection**

143 A unit of cord blood was thawed in a 37°C water bath, collected into a syringe, and
144 aliquoted into two or four syringes. In some cases, to remove dimethylsulphoxide, cord
145 blood was washed with a saline solution plus dextran and human albumin, resuspended in

146 10ml of the solution, and aliquoted into two syringes [22]. Decision on cord blood washing
147 was institution dependent. After local anesthesia, standard bone marrow aspiration needles
148 were inserted into the iliac bone. Intravenous anesthesia was not used. A small volume of
149 bone marrow was aspirated to confirm that the needle was inserted into the bone marrow
150 cavity. Subsequently, an aliquot of cord blood was gently injected. The procedure was
151 repeated for the remaining aliquots across the iliac crest. The adverse events associated
152 with intrabone injection were assessed by the National Cancer Institute-Common
153 Terminology Criteria for Adverse Events version 4.0.

154

155 **Donor chimerism**

156 Quantitative analysis of donor chimerism was performed using polymerase chain reaction
157 of short tandem repeat on days 28 and 56 after transplantation. Fluorescence in situ
158 hybridization for sex chromosomes was permitted for sex-mismatched transplantation.

159

160 **Definitions**

161 Engraftment was defined as the first of three consecutive days of neutrophil count $\geq 0.5 \times$

162 $10^9/L$ with donor chimerism $\geq 95\%$. The time to reticulocyte and platelet recoveries were

163 defined as the first of three consecutive days of reticulocyte $\geq 1\%$, platelet $\geq 20 \times 10^9/L$ and

164 platelet $\geq 50 \times 10^9/L$ without transfusion support. Engraftment failure was defined if

165 neutrophil count did not achieve $\geq 0.5 \times 10^9/L$ by day 60. Engraftment failure was also

166 defined if both of the following criteria were met before day 60; (1) the bone marrow was

167 severe hypoplastic after day 28, (2) donor chimerism of the T cell fraction was $\leq 50\%$ and

168 further decreased compared to the previous time point. Acute and chronic GVHD were

169 diagnosed and graded by clinicians at each institution according to the consensus criteria

170 [23, 24]. Acute myelogenous leukemia in the first or second remission, acute lymphoblastic

171 leukemia in the first remission, chronic myelogenous leukemia in the first chronic phase,

172 and myelodysplastic syndrome with refractory anemia or refractory anemia with ringed
173 sideroblasts were defined as standard-risk disease; all others were defined as high-risk
174 disease. Conditioning regimen was classified as myeloablative if at least one of the
175 following criteria was met: total body irradiation (TBI) >8 Gy, melphalan (Mel)
176 >140mg/m², intravenous busulfan (iv BU) ≥7.2mg/kg was used. Other conditioning
177 regimens were classified as nonmyeloablative [25].

178

179 **Statistical analysis**

180 The primary endpoint of this study was the probability of survival with neutrophil
181 engraftment on day 28 after transplantation. Fifty-eight patients were required to provide at
182 least 80% power to differentiate the primary endpoint of 78% with the width of the 95%
183 confidence interval (CI) at 15%. Assuming a 10% drop-out rate, 65 patients were required
184 for this study. The probabilities of hematological recoveries, GVHD, relapse, and

185 non-relapse mortality (NRM) were estimated based on cumulative incidence curves,
186 considering the following competing events: death without engraftment and second
187 transplantation for hematological recoveries, death or relapse without GVHD and second
188 transplantation for GVHD, death without relapse for relapse, and relapse for NRM.
189 Comparisons between the groups were performed using the Grey test. Overall survival after
190 transplantation was estimated according to the Kaplan-Meier method. All statistical
191 analyses were performed using EZR software version 1.41 [26]. *P*-values of less than 0.05
192 were regarded as statistically significant.

193

194 **Results**

195 **Patient characteristics**

196 Sixty-six patients were enrolled in this study. Two patients did not undergo intrabone CBT
197 due to deterioration of sepsis ($n = 1$) and cerebral infarction ($n = 1$) after enrollment. Of 64

198 patients who received intrabone CBT, two were assessed only for the safety of intrabone
199 injection, because the study monitoring conference concluded that an HCV-positive patient
200 who had received fewer than 2×10^7 /kg of cryopreserved TNC (n = 1) and a patient with
201 EB virus lymphoproliferative disorder (non-malignant disease) (n = 1) should be excluded
202 from evaluable patients for efficacy. The characteristics of 62 patients who were evaluable
203 for the efficacy of intrabone single-unit CBT are summarized in Table 1. The median age
204 was 48 years (range, 17–69 years). Thirty-eight patients received myeloablative
205 conditioning regimens including TBI-based regimen (n = 23) and BU-based regimen (n =
206 15), and 24 patients received non-myeloablative conditioning regimens including
207 fludarabine (Flu) + Mel-based regimen (n = 14), Flu + cyclophosphamide (CY)-based
208 regimen (n = 6), and Flu + BU-based regimen (n = 4). No patient received ATG as a GVHD
209 prophylaxis. Although 23 patients (37%) had anti-HLA antibody, no patient had
210 donor-specific anti-HLA antibody, which is reported to be associated with an increased risk

211 of engraftment failure [27]. The median number of cryopreserved TNC and CD34+ cells
212 were $2.57 \times 10^7/\text{kg}$ (range, $2.02\text{--}4.00 \times 10^7/\text{kg}$) and $0.99 \times 10^5/\text{kg}$ (range, $0.44\text{--}2.30 \times$
213 $10^5/\text{kg}$), respectively.

214

215 **Intrabone injection of cord blood**

216 Sixty-four patients received an intrabone injection of unwashed (n = 61) or washed (n = 3)
217 cord blood after local anesthesia. The number of the injection sites was two in four patients
218 and four in 60 patients. All injection-related adverse events were mild; nine were skin
219 reactions and 25 were pains at the injection site, all of which were resolved spontaneously.
220 No moderate or severer adverse event was observed.

221

222 **Hematological recovery**

223 Two patients died within 28 days after transplantation due to multiple organ failure (day 21)

224 and sepsis (day 26). The probability of survival with neutrophil engraftment on day 28 was
225 77.4% (95% CI, 67.0–85.8%). Finally, 50 patients achieved engraftment. The cumulative
226 incidence of engraftment on day 60 was 80.6% (95% CI, 68.2–88.6%), and the median time
227 to engraftment was 21 days (range, 15–31 days) (Fig. 1a). Two of 50 patients with
228 engraftment achieved $\geq 95\%$ of donor chimerism after day 28. One patient received
229 myeloablative conditioning regimen (iv BU 12.8mg/kg + CY 120mg/kg + TBI 3Gy), and
230 the other received nonmyeloablative conditioning regimen (Flu 200mg/m² + CY 50mg/kg +
231 TBI 3Gy). The cumulative incidences of reticulocytes $\geq 1\%$ on day 60, platelets $\geq 20 \times 10^9/L$
232 on day 100, and platelets $\geq 50 \times 10^9/L$ on day 100 were 79.0% (95% CI, 66.4–87.4%),
233 75.8% (62.6–84.9%), and 72.6% (59.4–82.1%), respectively (Fig. 1b-d). Among patients
234 with hematological recovery, the median time to reticulocytes $\geq 1\%$, platelets $\geq 20 \times 10^9/L$,
235 and platelets $\geq 50 \times 10^9/L$ were 30 (range, 18–77 days), 38 (18–81 days), and 45 (27–118
236 days) days, respectively. The numbers of cryopreserved TNC ($\geq 2.5 \times 10^7$ cells/kg vs. < 2.5

237 $\times 10^7$ cells/kg) and CD34+ cells ($\geq 1.0 \times 10^5$ cells/kg vs. $< 1.0 \times 10^5$ cells/kg) did not affect
238 neutrophil (Fig. 2a, b) and platelet recoveries (Fig. 3a, b). When patients were categorized
239 into four groups according to the combination of numbers of cryopreserved TNC and
240 CD34+ cells, no significant differences were observed among these groups (data not
241 shown). The degree of HLA mismatches in host-versus-graft direction (0–1 antigen
242 mismatch vs. 2 antigens mismatch) was not associated with neutrophil recovery (Fig. 2c)
243 and platelet recoveries (Fig. 3c). Neither preconditioning regimens nor GVHD prophylaxis
244 affected neutrophil and platelet recoveries (data not shown).

245

246 **GVHD, relapse, NRM and survival**

247 The cumulative incidences of grade II–IV and III–IV acute GVHD on day100 after
248 intrabone CBT were 29.0% (95% CI, 18.3–40.7%) and 6.5% (2.1–14.5%), respectively
249 (Fig. 4a, b). Twenty-four patients received treatment for acute GVHD using topical (n = 8)

250 or systemic (n = 16) corticosteroid. All of them responded to steroid therapy, and secondary
251 treatments were not required. The cumulative incidence of chronic GVHD at 1 year was
252 9.9% (95% CI, 4.0–19.1%).

253 The cumulative incidences of relapse and NRM at 1 year after intrabone CBT were
254 19.4% (95% CI, 10.6–30.1%) and 21.0% (11.8–31.9%), respectively.

255 Overall survival at 1 year after intrabone CBT for all 62 patients was 66.1% (95% CI,
256 52.9–76.4%) (Fig. 5). Of 10 patients with engraftment failure, nine underwent a second
257 transplantation from another cord blood (n = 7) or an HLA-haploidentical related donor (n
258 = 2), and five were alive at 1 year after intrabone CBT. One patient died of exacerbation of
259 sepsis during pretreatment prior to second transplantation. Of 50 patients who achieved
260 engraftment, 14 died after intrabone CBT. The most frequent cause of death was relapse of
261 hematological malignancies (n = 7). Other causes included non-infectious pulmonary
262 complications (n = 3), sinusoidal obstruction syndrome (n = 2), respiratory syncytial virus

263 infection (n = 1), and thrombotic microangiopathy (n = 1).

264

265 **Discussion**

266 We conducted the largest prospective study of intrabone single-unit CBT for adult patients

267 with hematological malignancies. The probability of survival with neutrophil engraftment

268 on day 28 (primary endpoint) was 77.4% (95% CI, 67.0–85.8%), which exceeded the

269 threshold value of 63%. The cumulative incidence of neutrophil engraftment on day 60 was

270 80.6%. In a recent large retrospective study for single-unit intravenous CBT comparing

271 European and Japanese populations, the cumulative incidences of neutrophil engraftment

272 on day 100 were 81% in the European cohort and 78% in the Japanese cohort. However,

273 those on day 28 were no more than 63% and 69%, respectively (numerical values based on

274 visual measurement of its Supplemental Figure) [28]. These data suggest that intrabone CBT

275 is effective in terms of early neutrophil engraftment rather than a high neutrophil

276 engraftment rate. In contrast, this study exhibited earlier platelet recovery (median time to
277 platelets $\geq 50 \times 10^9/L$, day 45) and higher platelet recovery rate (cumulative incidence of
278 platelets $\geq 50 \times 10^9/L$ on day100, 72.6%), compared to the Japanese historical data on
279 intravenous CBT (median time to platelets $\geq 50 \times 10^9/L$, day 78; cumulative incidence of
280 platelets $\geq 50 \times 10^9/L$ on day100, 58%) [16]. These data suggest that intrabone CBT is
281 effective in terms of both the speed and rate of platelet recovery.

282 The doses of TNC and CD34+ cells in transplanted cord blood unit are major factors
283 affecting the speed and/or rate of engraftment [29, 30]. Cord blood units comprising TNC
284 $\geq 2.5 \times 10^7/kg$ and CD34+ cells $\geq 1.5 \times 10^5/kg$ are recommended for single-unit CBT
285 according to the National Marrow Donor Program and the Center for International Blood
286 and Marrow Transplant Research [31]. However, a single cord blood unit with TNC $< 2.5 \times$
287 $10^7/kg$ is widely used in Japan, although a significant association between TNC dose $< 2.5 \times$
288 $10^7/kg$ and lower engraftment rate has been confirmed in a retrospective study of

289 single-unit CBT [28]. Some studies have shown a greater impact of the number of CD34+
290 cells for achievement of engraftment compared with the number of TNC [30, 32–34]. For
291 intrabone CBT, small-sized studies demonstrated an association of the TNC or CD34+ cell
292 dosage with neutrophil recovery [15, 18]. In the present study, neither TNC nor CD34+ cell
293 dose affected the speed and rate of engraftment and even the group that had a combination
294 of low TNC and low CD34+ cells showed no difference in neutrophil recovery from other
295 three groups. Thus, a question left unresolved is whether intrabone injection has the
296 potential to overcome the delayed and/or failed engraftment, especially in CBT with low
297 numbers of TNC and CD34+ cells.

298 The HLA disparity has also been reported to be a risk factor for the engraftment failure
299 in single-unit CBT [35–38]. However, the present study demonstrated no difference in both
300 neutrophil and platelet engraftment rate between 0–1 antigen-mismatched and 2
301 antigens-mismatched cord blood units. Thus, the HLA disparity may have no impact on the

302 engraftment in intrabone CBT.

303 In addition to the present study, five prospective studies of intrabone single-unit CBT
304 have been reported to date (Table 2). Relatively young patients underwent intrabone CBT
305 with myeloablative regimens in Europe [14, 18], while relatively elderly patients underwent
306 intrabone CBT with nonmyeloablative regimens in Japan, excluding this report [15–17].

307 The combination of CsA and MMF together with ATG was used as GVHD prophylaxis in
308 Europe, while the combination of CsA or Tac and short-term MTX or MMF without ATG
309 was used in Japan. Interestingly, three reports from Japan demonstrated faster neutrophil
310 engraftment compared with the other reports [15–17], which might be due to the use of
311 nonmyeloablative preconditioning [39]. Two reports from Europe demonstrated lower
312 incidence of acute GVHD compared with the other reports [14, 18], which might be due to
313 the use of ATG as GVHD prophylaxis [40].

314 The use of ATG as GVHD prophylaxis for CBT is controversial [41]. ATG has been

315 widely used since the early phases of CBT development [42, 43]. However, the exposure to
316 ATG after CBT has a detrimental effect on early T-cell immune reconstitution [44, 45]. A
317 recent retrospective study in Japan demonstrated a negative impact of ATG on NRM after
318 intravenous single-unit CBT [46]. A retrospective study in Europe comparing intrabone
319 single-unit CBT and intravenous double-unit CBT demonstrated a significantly lower
320 incidence of acute GVHD in intrabone CBT [47]. In the present study, 29% of patients
321 developed grade II or higher acute GVHD, however, all patients responded to first-line
322 steroid therapy. Taken together, it is critical to determine whether ATG provides benefits to
323 patients undergoing intrabone single-unit CBT in terms of GVHD prophylaxis, immune
324 reconstitution, NRM and survival.

325 In the previous prospective randomized study to compare intrabone infusion of bone
326 marrow with intravenous infusion, the infused cells were traced by bone marrow
327 scintigraphy [48]. The bone marrow cells that had been infused intrabone first passed the

328 lung and then were distributed more widely in the human body. In fact, there were no
329 differences in engraftment, GVHD or survival between the intrabone and intravenous bone
330 marrow transplantation [48,49]. However, there is a critical difference between CBT and
331 bone marrow transplantation. The former is characterized by delayed engraftment, lower
332 engraftment rate, infusion of small-volume of thawed cord blood (< 20~25 mL), etc., and
333 the latter is characterized by surefire engraftment, large-volume of bone marrow
334 (approximately 600~1000mL), etc. Further investigation to compare the behavior of cord
335 blood graft after intrabone and intravenous injection in human body should be performed.

336 The major advantages of intrabone CBT compared to double-unit CBT and ex vivo
337 expanded CBT are an inexpensive method and easy technique, and additional cord blood
338 units, recombinant cytokines, drugs, and cell processing technique and facilities are all not
339 required. The present study as well as a previous study [17] confirmed safety of the
340 injection of unwashed cord blood into the bone marrow cavity. Further efforts to optimize

341 preconditioning regimen, GVHD prophylaxis, and cord blood selection for intrabone

342 single-unit CBT is needed.

507 **Figure legends**

508 **Fig. 1.** Hematological recovery after intrabone single-unit CBT without ATG. Cumulative
509 incidences of neutrophil $\geq 0.5 \times 10^9/L$ (a), reticulocytes $\geq 1\%$ (b), platelet $\geq 20 \times 10^9/L$ (c),
510 and platelet $\geq 50 \times 10^9/L$ (d) are shown.

511

512 **Fig. 2.** Neutrophil recoveries according to the cell dose and HLA compatibility. Cumulative
513 incidences of neutrophil $\geq 0.5 \times 10^9/L$ according to total nucleated cell dose (high: $\geq 2.5 \times$
514 10^7 cells/kg, low: $< 2.5 \times 10^7$ cells/kg) (a), CD34+ cell dose (high: $\geq 1.0 \times 10^5$ cells/kg, low:
515 $< 1.0 \times 10^5$ cells/kg) (b), and the number of HLA-A, -B, and -DR antigen mismatches (c) are
516 shown.

517

518 **Fig. 3.** Platelet recoveries according to the cell dose and HLA compatibility. Cumulative
519 incidences of platelets $\geq 50 \times 10^9/L$ according to total nucleated cell dose (high: $\geq 2.5 \times 10^7$

520 cells/kg, low: $<2.5 \times 10^7$ cells/kg) (a), CD34+ cell dose (high: $\geq 1.0 \times 10^5$ cells/kg, low: <1.0
521 $\times 10^5$ cells/kg) (b), and the number of HLA-A, -B, and -DR antigen mismatches (c) are
522 shown.

523

524 **Fig. 4.** Acute GVHD after intrabone single-unit CBT without ATG. Cumulative incidences
525 of grade II–IV (a) and grade III–IV (b) acute GVHD are shown.

526

527 **Fig. 5.** Overall survival for all patients.

Table 1 Patient characteristics (n = 62)

Age at transplant, median (range), y	48 (17–69)
Sex, n	
Male/female	31/31
Disease, n (%)	
AML	33 (53%)
ALL	12 (19%)
MDS	8 (13%)
CML	3 (5%)
ATLL	2 (3%)
T-LBL	2 (3%)
MPAL	1 (2%)
CMML	1 (2%)
Disease risk, n (%)	
Standard-risk [†]	35 (56%)
High-risk [‡]	27 (44%)
Preconditioning, n (%)	
Myeloablative	38 (61%)
Nonmyeloablative	24 (39%)
GVHD prophylaxis, n (%)	
CsA + sMTX	11 (18%)
CsA + MMF	3 (5%)
Tac + sMTX	42 (67%)
Tac + MMF	6 (10%)
HLA compatibility, n (%)	
Host-versus-graft direction	
6/6	5 (8%)
5/6	16 (26%)
4/6	41 (66%)
Graft-versus-host direction	
6/6	5 (8%)
5/6	20 (32%)
4/6	37 (60%)
Cord blood	
TNC, median (range), × 10 ⁷ /kg	2.57 (2.02–4.00)
CD34+ cells, median (range), × 10 ⁵ /kg	0.99 (0.44–2.30)

AML, acute myelogenous leukemia; ALL, acute lymphoblastic leukemia; MDS, myelodysplastic syndrome; CML, chronic myelogenous leukemia; ATLL, adult T-cell leukemia/lymphoma; T-LBL, T-cell lymphoblastic lymphoma; MPAL, mixed phenotype acute leukemia; CMML, chronic myelomonocytic leukemia; GVHD, graft-versus-host disease; CsA, cyclosporine; sMTX, short-term methotrexate; MMF, mycophenolate mofetil; Tac, tacrolimus; TNC, total nucleated cells

[†] AML in the first or second remission, ALL in the first remission, CML in the first chronic phase, and MDS with refractory anemia or refractory anemia with ringed sideroblasts; [‡] All other diseases than standard-risk disease
